Efavirenz (see structure in Figure 64–5) is an NNRTI with potent activity against HIV-1. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. Efavirenz has been used widely because of its convenience, effectiveness, and long-term tolerability. Especially popular is the once-daily, single-pill coformulation of efavirenz, TDF, and emtricitabine. Efavirenz plus two NRTIs was a preferred regimen for naïve patients, but it is being replaced in many parts of the world by regimens with better tolerability. A 400-mg daily dose of efavirenz may be equally efficacious and better tolerated than the standard 600-mg dose (ENCORE1 Study Group, 2014).

$^a$Reported mean values in adults with normal renal and hepatic function.

$^b$Values at steady state after multiple oral doses.
Efavirenz can be safely combined with rifampin and is useful in patients also being treated for tuberculosis. Efavirenz is approved for adult and pediatric patients 3 years and older and weighing at least 10 kg.

**ADME.** Table 64–3 summarizes the pharmacokinetic data for this agent. Efavirenz is well absorbed from the GI tract, but there is diminished absorption of the drug with increasing doses. Bioavailability (AUC) is increased by 22% with a high-fat meal. Efavirenz is more than 99% bound to plasma proteins, and, as a consequence, has a low CSF-to-plasma ratio of 0.01. The drug should be taken initially on an empty stomach at bedtime to reduce side effects. The long elimination \( t_{1/2} \) permits once-daily dosing.

**Untoward Effects and Drug Interactions.** The most important adverse effects of efavirenz involve the CNS. Up to 53% of patients report some CNS or psychiatric side effects, but fewer than 5% discontinue the drug for this reason. Patients commonly report dizziness, impaired concentration, dysphoria, vivid or disturbing dreams, and insomnia. CNS side effects generally become more tolerable and resolve within the first 4 weeks of therapy. Rash occurs frequently with efavirenz (27%), usually in the first few weeks of treatment, resolving spontaneously and rarely requiring drug discontinuation. Life-threatening skin eruptions such as Stevens-Johnson syndrome are rare (de Bethune, 2010). Other side effects reported with efavirenz include headache, increased hepatic transaminases, and elevated serum cholesterol. Efavirenz is the only antiretroviral drug that is teratogenic in primates, but careful clinical studies suggested that it is no more teratogenic in humans than other antiretroviral drugs (Ford et al., 2014). Efavirenz is a moderate inducer of hepatic enzymes, especially CYP3A4, but also a weak to moderate CYP inhibitor. Efavirenz decreases concentrations of phenobarbital, phenytoin, and carbamazepine; the methadone AUC is reduced by 55%–66% at steady state. Efavirenz reduces the rifabutin AUC by about 38%. Efavirenz has a variable effect on HIV PIs. Indinavir, saquinavir, and amprenavir concentrations are reduced; ritonavir and nelfinavir concentrations are increased. Drugs that induce CYPs 2B6 or 3A4 (e.g., phenobarbital, phenytoin, and carbamazepine) would be expected to increase the clearance of efavirenz and should be avoided (de Bethune, 2010).

**Rilpivirine**

Rilpivirine is a diarylpyrimidine NNRTI with potent activity against HIV-1. Table 64–3 presents some of the drug's pharmacokinetic values. The drug should be used only in combination with other effective agents and should not be added as the sole new agent to a failing regimen. Rilpivirine has the best side-effect profile of available NNRTIs and has few or no CNS side effects compared to efavirenz. Rilpivirine retains efficacy against many HIV strains that are resistant to efavirenz and other earlier NNRTIs. However, higher concentrations of rilpivirine are associated with prolongation of the QTc interval and, at the approved dose of 25 mg per day, is less effective than efavirenz in patients with baseline viral load greater than 100,000 copies/mL or CD4 count below 200 cells/mm³ (Sharma and Saravolatz, 2013). Failure of a rilpivirine-containing regimen generally results in resistance of the virus aspartyl protease (\( \text{aspartic acid residue that is essential for catalysis.} \))

**Adjunctive Therapy and Drug Interactions.** Rash (<5%) occurs less frequently with rilpivirine than with other NNRTIs. Although CNS adverse effects are much less common with rilpivirine than with efavirenz, depressive symptoms have been reported, including in pediatric and adolescent patients. Elevated hepatic transaminases may occur, especially in those with underlying HBV or hepatitis C virus infection. Rilpivirine is considered pregnancy category B by the FDA.

Rilpivirine concentrations can be reduced by coadministered CYP inducers, and this drug should not be given with rifampin; anticonvulsants such as carbamazepine, phenobarbital, or phenytoin; or any products containing St. John's wort. At the 25-mg daily dose, rilpivirine is not a clinically significant inhibitor or inducer of hepatic enzymes. Because rilpivirine can prolong the QTc in a concentration-dependent fashion, caution is advised when combining this drug with any known CYP3A4 inhibitors or other drugs that can increase rilpivirine concentrations or with other drugs known to prolong the QTc.

**Etravirine**

Etravirine is a diarylpyrimidine NNRTI that is active against HIV-1. The drug is unique in its ability to inhibit reverse transcriptase that is resistant to other NNRTIs. Etravirine appears to have conformational and positional flexibility in the NNRTI-binding pocket that allow it to inhibit the function of the HIV-1 reverse transcriptase in the presence of common NNRTI resistance mutations (de Bethune, 2010). Etravirine is approved for use only in treatment-experienced adults and children 6 years or older with viral strains resistant to another NNRTI. NNRTI-experienced patients should not receive etravirine plus NRTIs alone.

**ADME.** Table 64–3 summarizes the pharmacokinetic data for this agent. Food increases the etravirine AUC by about 50%; thus, the drug should be administered with food. Methyl- and dimethyl-hydroxylated metabolites are produced in the liver primarily by CYPs 3A4, 2C9, and 2C19, accounting for most of the elimination of this drug.

**Untoward Effects and Drug Interactions.** The only notable side effect of etravirine is rash (17% vs. placebo value of 9%), usually occurring within a few weeks of starting therapy and resolving within 1–3 weeks. Severe rash, including Stevens-Johnson syndrome and toxic epidermal necrolysis, have been reported (de Bethune, 2010). Etravirine is an inducer of CYP3A4 and glucuronosyl transferases and an inhibitor of CYPs 2C9 and 2C19; it can therefore be involved in a number of clinically significant pharmacokinetic drug interactions. Etravirine can be combined with darunavir/ritonavir, lopinavir/ritonavir, and saquinavir/ritonavir without the need for dose adjustments. The dose of maraviroc should be doubled when these two drugs are combined. Etravirine should not be administered with tipranavir/ritonavir, fosamprenavir/ritonavir, or atazanavir/ritonavir in the absence of better data to guide dosing. Etravirine should not be combined with other NNRTIs. Unlike other NNRTIs, etravirine does not appear to alter the clearance of methadone.

**Delavirdine**

Delavirdine is a bisheteroarylpiperazine NNRTI that selectively inhibits HIV-1. This agent shares resistance mutations with efavirenz and nevirapine.

**ADME.** Delavirdine is rarely used because it has to be dosed thrice daily (de Bethune, 2010). The drug is well absorbed, especially at acidic pH (pH < 2). Antacids, histamine H₂ receptor antagonists, proton pump inhibitors, and aloe vera can decrease its absorption. The drug can be administered irrespective of concurrent food.

**Untoward Effects and Drug Interactions.** The most common side effect of delavirdine is rash (18%–36%), usually in the first few weeks of treatment and often resolving despite continued therapy. Severe dermatitis, including erythema multiforme and Stevens-Johnson syndrome, is rare. Elevated hepatic transaminases and hepatic failure also have been reported, as has neutropenia (rare). Delavirdine is both a substrate for and an inhibitor of CYP3A4 and can alter the metabolism of other CYP3A4 substrates. Delavirdine increases the plasma concentrations of most HIV PIs.

**HIV Protease Inhibitors**

**Overview**

The HIV PIs are peptide-like chemicals that competitively inhibit the action of the virus aspartyl protease (Figure 64–6). This protease is a homodimer consisting of two 99-amino-acid monomers; each monomer contributes an aspartic acid residue that is essential for catalysis. The preferred cleavage site for this enzyme is the N-terminal side of proline...
residues, especially between phenylalanine and proline. Human aspartyl proteases (i.e., renin, pepsin, gastricsin, and cathepsins D and E) contain only one polypeptide chain and are not significantly inhibited by HIV PIs (Wensing et al., 2010).

Table 64–4 summarizes pharmacokinetic data for these agents. Clearance is mainly through hepatic oxidative metabolism. All except nelfinavir are metabolized predominantly by CYP3A4 (and nelfinavir's major metabolite is cleared by CYP3A4). All approved HIV PIs have the potential for metabolic drug interactions. Most of these drugs inhibit CYP3A4 at clinically achieved concentrations, although the magnitude of inhibition varies greatly, with ritonavir by far the most potent. It is now a common practice to combine HIV PIs with a low dose of ritonavir or cobicistat to take advantage of either drug's remarkable capacity to inhibit CYP3A4 metabolism.

**“Boosting” PIs With a CYP Inhibitor.** The metabolic clearance of HIV PIs is inhibited by cobicistat, a ritonavir analogue that lacks antiretroviral activity and that was developed for exclusive use as a pharmacokinetic enhancer (Sherman et al., 2015). Cobicistat is a potent and selective inhibitor of CYP 3A4 but is better tolerated than ritonavir and is not a CYP enzyme inducer. Doses of ritonavir of 100 or 200 mg once or twice daily, or cobicistat 150 mg daily, are sufficient to inhibit CYP3A4 and increase (“boost”) the concentrations of most concurrently administered CYP3A4 substrates. The enhanced pharmacokinetic profile of HIV PIs administered with ritonavir or cobicistat reflects inhibition of both first-pass and systemic clearance, resulting in improved oral bioavailability and a longer elimination t½ of the coadministered drug. This allows a reduction in both drug dose and dosing frequency while increasing systemic concentrations. Combinations of either atazanavir, darunavir, fosamprenavir, lopinavir with ritonavir, or cobicistat with atazanavir or darunavir are approved for once-daily administration.

**Other Shared Properties of PIs.** Most HIV PIs are substrates for the P-glycoprotein efflux pump (see Chapter 5). These agents generally penetrate less well into semen than do NRTIs and NNRTIs. HIV PIs have high interindividual serum concentration variability that may reflect differential activity of intestinal and hepatic CYPs. The speed with which HIV develops resistance to unboosted PIs is intermediate between that of nucleoside analogues and NNRTIs. Initial (primary) resistance mutations in the enzymatic active site confer only a 3- to 5-fold drop in sensitivity to most drugs; these are followed by secondary mutations often distant from the active site that compensate for the reduction in proteolytic efficiency. Accumulation of secondary resistance mutations increases the likelihood of cross-resistance to other PIs. This relatively favorable resistance profile makes HIV PIs attractive agents for use as second-line therapy in patients who have failed previous antiretroviral regimens (Wensing et al., 2010).

Gastrointestinal side effects, including nausea, vomiting, and diarrhea, were common with older HIV PIs but are much less likely to occur with the newer drugs atazanavir and darunavir.

Saquinavir
Saquinavir is a peptidomimetic hydroxysteridameline that inhibits replication of both HIV-1 and HIV-2 (Figure 64–6). Typical of HIV PIs, high-level resistance requires accumulation of multiple resistance mutations. The drug is available as a hard-gelatin capsule. When combined with ritonavir and nucleoside analogues, saquinavir produces viral load reductions comparable with those of other HIV PI regimens (Wensing et al., 2010).

ADME. See Table 64–4 for the pharmacokinetic profile of this agent. Fractional oral bioavailability is low owing mainly to first-pass metabolism, so this drug should always be given in combination with ritonavir. Low doses of ritonavir increase the saquinavir steady-state AUC by 20–30-fold. Substances that inhibit intestinal but not hepatic CYP3A4 (e.g., grapefruit juice) can increase the saquinavir AUC by about 3-fold.

Unoward Effects and Drug Interactions. The most frequent side effects of saquinavir are GI: nausea, vomiting, diarrhea, and abdomi- nal discomfort. Most side effects of saquinavir are mild and short lived, although long-term use is associated with lipodystrophy.

Saquinavir clearance is increased with CYP3A4 induction. Coadministra- tion of inducers of CYP3A4 such as rifampin, phenytoin, or carbamazepine lowers saquinavir concentrations and should be avoided. The effect of nevirapine or efavirenz on saquinavir may be reversed with ritonavir.

Ritonavir
Ritonavir is a peptidomimetic HIV PI designed to complement the C2 axis of symmetry of the enzyme active site. Ritonavir is active against both HIV-1 and HIV-2 (perhaps slightly less active against HIV-2). Ritonavir is mostly used as a pharmacokinetic enhancer (CYP3A4 inhibitor); the low doses used for this purpose are not known to induce ritonavir resistance mutations. The drug is used infrequently as the sole PI in combination regimens because of GI toxicity (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. Interindividual variability in pharmacokinetics is high, with variability exceeding 6-fold in trough concentrations amongst patients given 600 mg of ritonavir every 12 h as capsules.

Unoward Effects and Drug Interactions. The major side effects of ritonavir are GI and include dose-dependent nausea, vomiting, diarr- hea, anorexia, abdominal pain, and taste perversion. GI toxicity may be reduced if the drug is taken with meals. Peripheral and perioral paresthesias can occur at the therapeutic dose of 600 mg twice daily. These side effects generally abate within a few weeks of starting therapy. Ritonavir also causes dose-dependent elevations in serum total cholesterol and triglycerides, as well as other signs of lipodystrophy.

Ritonavir is one of the most potent known inhibitors of CYP3A4. Thus, ritonavir must be used with caution in combination with any CYP3A4 substrate and should not be combined with drugs that have a narrow therapeutic index, such as midazolam, triazolam, fentanyl, and ergot derivatives. Ritonavir is a mixed competitive and irreversible inhibitor of CYP3A4; its effects can persist for 2–3 days after the drug is discontinued (Washington et al., 2003). Ritonavir is also a weak inhibitor of CYP2D6. Potential inducers of CYP3A4 activity such as rifampin may lower ritonavir concentrations and should be avoided or the dosages adjusted. Capsule and solution formulations of ritonavir contain alcohol and should not be administered with disulfiram or metronidazole. Ritonavir is also a mod- erate inducer of CYP3A4, glucuronosyl-S-transferase, and possibly other hepatic enzymes and drug transport proteins. The concentrations of some drugs therefore will be decreased in the presence of ritonavir. Ritonavir reduces the ethinyl estradiol AUC by 40%; thus, alternative forms of contraception should be used.

Use of Ritonavir as a CYP3A4 Inhibitor. Ritonavir inhibits the metab- olism of all current HIV PIs and is frequently used in combination with most of these drugs (with the exception of nelfinavir) to enhance their pharmacokinetic profiles and allow a reduction in their doses and dosing frequencies. Ritonavir also overcomes the deleterious effect of food on indinavir bioavailability. Low doses of ritonavir (100 or 200 mg once or twice daily) are just as effective at inhibiting CYP3A4 and are much better tolerated than the 600-mg twice-daily dose (Wensing et al., 2010).

Fosamprenavir
Fosamprenavir is a phosphonooxy prodrug of amprenavir that has increased water solubility and improved oral bioavailability. Fosamprena- vir is as effective, and generally better tolerated, than amprenavir, and as a result, amprenavir is no longer marketed (Wensing et al., 2010). The drug is active against both HIV-1 and HIV-2. Fosamprenavir has long-term viro- logic benefit in treatment-naive and treatment-experienced patients, with or without ritonavir, in combination with nucleoside analogues. Twice- daily fosamprenavir/ritonavir produces virologic outcomes equivalent to lopinavir/ritonavir in both treatment-naive and treatment-experienced patients. Fosamprenavir is approved for use in treatment-naive pediatric patients 2 years or older and treatment-experienced patients 6 or more years of age, at a dose of 30 mg/kg twice daily or 18 mg/kg plus ritonavir 3 mg/kg twice daily. Amprenavir’s primary resistance mutation occurs at HIV protease codon 50. Primary resistance occurs less frequently at codon 84.

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. The phosphorylated prodrug is about 2000 times more water soluble than amprenavir. Fosamprenavir is dephosphorylated rapidly to amprenavir in the intestinal mucosa (Wensing et al., 2010). Meals have no significant effect on fosamprenavir pharmacokinetics.

Untoward Effects and Drug Interactions. The most common adverse effects involve the GI tract and include diarrhea, nausea, and vomit- ing. Hyperglycemia, fatigue, paresthesias, and headache also have been reported. Fosamprenavir can produce skin eruptions; moderate-to-severe rash (in up to 8% of recipients) may occur within 2 weeks of starting therapy. Fosamprenavir has fewer effects on plasma lipid profiles than lopinavir-based regimens.

Inducers of hepatic CYP3A4 activity (e.g., rifampin and efavirenz) may lower plasma amprenavir concentrations. Because amprenavir is both an inhibitor and inducer of CYP3A4, pharmacokinetic drug interactions can occur and may be unpredictable, especially if the drug is given without ritonavir.

Lopinavir
Lopinavir is structurally similar to ritonavir but is 3- to 10-fold more potent against HIV-1. This agent is active against both HIV-1 and HIV-2. Lopinavir is available only in coformulation with low doses of ritonavir used as a CYP3A4 inhibitor. Lopinavir has antiretroviral activity comparable with that of other potent HIV PIs and better than that of nelfinavir. Lopinavir also has considerable and sustained antiretroviral activity in patients who have failed previous HIV PI-containing regimens (Wensing et al., 2010).

Treatment-naive patients who fail a first regimen containing lopinavir generally do not have detectable HIV protease mutations but may have genetic resistance to the other drugs in the regimen (Wensing et al., 2010). For treatment-experienced patients, accumulation of four or more HIV PI resistance mutations is associated with a reduced likelihood of virus suppression after starting lopinavir.

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. The adult lopinavir/ritonavir dose is 400/100 mg (2 tablets) twice daily, or 800/200 mg (4 tablets) once daily. Lopinavir/ritonavir should not be dosed once daily in treatment-experienced patients. Lopinavir/ritonavir is approved for use in pediatric patients 14 days or older, with dosing based on either weight or body surface area. A pediatric tablet formulation is available for use in children more than 6 months of age. Lopinavir is absorbed rapidly after oral administration. Food has a minimal effect on bioavailability. Although the tablets contain lopinavir/ritonavir in a fixed 4:1 ratio, the observed plasma concentration ratio for these two drugs following oral administration is nearly 20:1, reflecting the sensitivity of lopinavir to the inhibitory effect of ritonavir on CYP3A4. Both lopina- vir and ritonavir are highly bound to plasma proteins, mainly to α1-acid glycoprotein, and have a low fractional penetration into CSF and semen.
Untoward Effects and Drug Interactions. The most common adverse events reported with the lopinavir/ritonavir coformulation are GI: loose stools, diarrhea, nausea, and vomiting. Laboratory abnormalities include elevated total cholesterol and triglycerides. It is unclear whether these side effects are due to ritonavir, lopinavir, or both.

Concomitant administration of agents that induce CYP3A4, such as rifampin, may lower plasma lopinavir concentrations considerably. St. John's wort is a known inducer of CYP3A4, leading to lower concentrations of lopinavir and possible loss of antiviral effectiveness. Co administration of other antiretrovirals that can induce CYP3A4 (e.g., amprapenia, nevirapine, or efavirenz) may require increasing the dose of lopinavir. The liquid formulation of lopinavir contains 42% ethanol and should not be administered with disulfiram or metronidazole. Ritonavir is also a moderate CYP inducer at the dose employed in the coformulation and can adversely decrease concentrations of some coadministered drugs (e.g., oral contraceptives). There is no direct proof that lopinavir is a CYP inducer in vivo; however, concentrations of some coadministered drugs (e.g., amprapenia and phenytoin) are lower with the lopinavir/ritonavir coformulation than would have been expected with low-dose ritonavir alone.

Atazanavir
Atazanavir is an azapeptide PI that is active against both HIV-1 and HIV-2. A coformulation with cobicistat (EVOTAZ) is also available.

Therapeutic Use. Atazanavir, with or without ritonavir, is approved for treatment of adults and pediatric patients more than 3 months of age and weighing at least 5 kg; in the pediatric population, dosing is based on weight. In treatment-experienced adult patients, atazanavir 400 mg once daily without ritonavir was inferior to the lopinavir/ritonavir coformulation given twice daily. The combination of atazanavir and low-dose ritonavir had a similar viral load effect as the lopinavir/ritonavir coformulation in one study, suggesting that this drug should be combined with ritonavir or cobicistat in treatment-experienced patients and perhaps in treatment-naive patients with high baseline viral loads. The primary advantage of atazanavir resistance mutation occurs at HIV protease codon 50 and confers about 9-fold decreased susceptibility. High-level resistance is more likely if five or more additional mutations are present (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. Atazanavir is absorbed rapidly after oral administration. A light meal decreases the AUC; thus, the drug should be administered with food. Absorption is pH dependent, and proton pump inhibitors or other acid-reducing agents substantially reduce atazanavir concentrations after oral dosing (Wensing et al., 2010). The mean elimination t1/2 of atazanavir increases with dose, from 7 h at the standard 400-mg once-daily dose to nearly 10 h at a dose of 600 mg. The atazanavir dose is 400 mg once daily in adults if given without a pharmacokinetic enhancer (ritonavir or cobicistat) and 300 mg if given with ritonavir 100 mg or cobicistat 150 mg. The drug is present in CSF at less than 3% of plasma concentrations but has excellent penetration into seminal fluid.

Untoward Effects and Drug Interactions. Atazanavir frequently causes un conjugated hyperbilirubinemia, although this is not associated with hepatotoxicity. Postmarketing reports include hepatic adverse reactions of cholecytitis, cholelithiasis, cholestasis, and other hepatic function abnormalities. Atazanavir can precipitate in urine, causing increased risk of kidney stones. Other side effects reported with atazanavir include diarrhea and nausea, mainly during the first few weeks of therapy. Overall, 6% of patients discontinue atazanavir because of side effects during 48 weeks of treatment. Patients treated with atazanavir have significantly lower fasting triglyceride and cholesterol concentrations than patients treated with nelfinavir, lopinavir, or efavirenz.

Because atazanavir is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., rifampin) is contraindicated. Atazanavir is also a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Atazanavir is a moderate UGT1A1 inhibitor and increases the raltegravir AUC by 41%–72%. Ritonavir significantly increases the atazanavir AUC and reduces atazanavir systemic clearance. Concomitantly administered proton pump inhibitors reduce atazanavir concentrations substantially. Proton pump inhibitors and H2 receptor antagonists should be avoided in patients receiving atazanavir without ritonavir (Wensing et al., 2010).

Darunavir
Darunavir is a nonpeptidic PI that is active against both HIV-1 and HIV-2. Darunavir binds tightly but reversibly to the active site of HIV protease but has also been shown to prevent protease dimerization. At least three darunavir-associated resistance mutations are required to confer resistance (Wensing et al., 2010). Darunavir in combination with ritonavir is approved for use in HIV-infected adults and children more than 3 years old. A coformulation with cobicistat is also available.

ADME. Table 64–4 presents some pharmacokinetic data on this agent. Darunavir/ritonavir can be used as a once-daily (800-/100-mg) regimen with nucleosides in treatment-naive adults or as a twice-daily (600-/100-mg) regimen in treatment-experienced adults with at least one darunavir-associated resistance mutation; this drug should be taken with food. Pediatric dosing is based on body weight. Darunavir is absorbed rapidly after oral administration with ritonavir, with peak concentrations occurring after 2–4 h. Ritonavir increases darunavir bioavailability by up to 14-fold. When combined with ritonavir, the mean elimination t1/2 of darunavir is about 15 h, and the AUC is increased by an order of magnitude.

Untoward Effects and Drug Interactions. Because darunavir must be combined with cobicistat or a low dose of ritonavir, drug administration can be accompanied by all of the side effects caused by those agents, including drug interactions and GI complaints in up to 20% of patients taking ritonavir. Darunavir, like fosamprenavir, contains a sulfa moiety, and rash has been reported in up to 10% of recipients. Darunavir/ritonavir is associated with increases in plasma triglycerides and cholesterol, although the magnitude of increase is lower than that seen with lopinavir/ritonavir. Darunavir has been associated with episodes of hepatotoxicity.

Because darunavir is metabolized by CYP3A4, concomitant administration of agents that induce CYP3A4 (e.g., rifampin) is contraindicated. The drug interaction profiles of darunavir/ritonavir or darunavir/cobicistat are dominated by those expected with the pharmacokinetic enhancer. Darunavir/ritonavir 600/100 twice daily increases the maraviroc AUC by 340%; the maraviroc dose should be reduced to 150 mg twice daily when combined with darunavir (Wensing et al., 2010).

Indinavir
Indinavir, a peptidomimetic HIV PI, lacks significant advantages over other HIV PIs and is no longer widely prescribed because of problems with nephro lithiasis and other nephrotoxicities (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of indinavir. The drug is absorbed rapidly after oral administration, with peak concentrations achieved in about 1 h. High-calorie, high-fat meals reduce the Cmax by 75%; thus, indinavir must be taken with ritonavir or while fasting or with a light low-fat meal. Indinavir has the lowest protein binding of the HIV PIs; as a consequence, indinavir has higher fractional CSF penetration than other drugs in this class. The short t1/2 of indinavir makes thrice-daily (every 8 h) dosing necessary unless the drug is combined with ritonavir, which increases indinavir clearance, allowing twice-daily dosing regardless of meals.
Untoward Effects and Drug Interactions. A unique adverse effect of indinavir is crystalluria and nephrolithiasis, stemming from the poor solubility of the drug (lower at pH 7.4 than at pH 3.5). Nephrolithiasis occurs in about 3% of patients. Patients must drink sufficient fluids to maintain dilute urine and prevent renal complications. Risk of nephrolithiasis is related to higher plasma drug concentrations. Patients taking indinavir should drink at least 2 L of water daily to prevent renal complications. This is especially problematic for those who live in warm climates. Because indinavir solubility decreases at higher pH, antacids or other buffering agents should not be taken at the same time. Didanosine formulations containing an antacid buffer should not be taken within 2 h before or 1 h after indinavir. This agent is metabolized by CYP3A4 and is a moderately potent CYP3A4 inhibitor; thus, indinavir should not be coadministered with other CYP3A4 substrates that have narrow therapeutic indices.

Indinavir frequently causes unconjugated hyperbilirubinemia. This is generally asymptomatic and not associated with serious long-term sequelae. Indinavir has been associated with hyperglycemia and can induce insulin resistance. Dermatologic complications have been reported, including hair loss, dry skin, dry and cracked lips, and ingrown toenails.

Nelfinavir
Nelfinavir is a nonpeptidic PI that is active against both HIV-1 and HIV-2. Nelfinavir is approved for the treatment of HIV infection in adults and children in combination with other antiretroviral drugs. Long-term virologic suppression with nelfinavir-based combination regimens is significantly inferior to lopinavir/ritonavir, atazanavir, or efavirenz-based regimens. Nelfinavir is rarely used because of the availability of better tolerated and more efficacious PIs (Wensing et al., 2010).

The primary nelfinavir resistance mutation (D30N) is unique to this drug and results in a 7-fold decrease in susceptibility. Isolates with only this mutation retain full sensitivity to other HIV PIs. Less commonly, a primary resistance mutation occurs at position 90, which can confer cross-resistance. Secondary resistance mutations can accumulate, and these are associated with further resistance to nelfinavir, as well as cross-resistance to other HIV PIs.

ADME. The pharmacokinetic profile of this agent appears in Table 64–4. A moderate-fat meal increases the AUC 2- to 3-fold; higher concentrations are achieved with high-fat meals. Intraindividual and interindividual variabilities in plasma nelfinavir concentrations are large as a consequence of variable absorption. Nelfinavir is the only HIV PI whose pharmacokinetics are not substantially improved with ritonavir. Its major hydroxy-1-butylamide metabolite, M8, the only known active metabolite of any HIV PI, is formed by CYP2C19; its antiretroviral activity rivals that of the parent drug. Nelfinavir induces its own metabolism.

Untoward Effects and Drug Interactions. The most important side effects of nelfinavir are diarrhea and loose stools, which resolve in most patients within the first 4 weeks of therapy. Otherwise, nelfinavir is generally well tolerated. It has been associated with glucose intolerance, elevated cholesterol levels, and elevated triglycerides.

Because nelfinavir is metabolized by CYPs 2C19 and 3A4, concomitant administration of agents that induce these enzymes may be contraindicated (as with rifampin) or may necessitate an increased nelfinavir dose (as with rifabutin). Nelfinavir is a moderate inhibitor of CYP3A4 and may alter plasma concentrations of other CYP3A4 substrates. Nelfinavir also induces hepatic drug-metabolizing enzymes, reducing the AUC of ethinyl estradiol (↓ 47%) and norethindrone (↓ 18%). Combination oral contraceptives therefore should not be used as the sole form of contraception in patients taking nelfinavir. Nelfinavir reduces the zidovudine AUC by 35%.

Tipranavir
Tipranavir is a nonpeptidic PI that is active against both HIV-1 and HIV-2. Tipranavir is approved for use only in treatment-experienced adult and pediatric patients whose HIV is resistant to one or more PIs. Combining tipranavir/ritonavir with at least one other active antiretroviral drug, usually enfuvirtide, greatly improves virologic responses. Tipranavir/ritonavir is approved for use in adults and pediatric patients more than 2 years of age, with pediatric dosing based on weight or body surface area. Because most HIV strains sensitive to tipranavir are also sensitive to darunavir, darunavir is preferred for most treatment-experienced patients because of its better tolerability and toxicity profile (Wensing et al., 2010).

ADME. Table 64–4 summarizes the pharmacokinetic profile of this agent. Tipranavir must be administered with ritonavir because of poor oral bioavailability. The recommended regimen of tipranavir/ritonavir 500/200 mg twice daily includes a ritonavir dose higher than that of other boosted HIV PIs; lower doses of ritonavir should not be used. Food does not alter pharmacokinetics in the presence of ritonavir but may reduce GI side effects.

Untoward Effects and Drug Interactions. Tipranavir use has been associated rarely with fatal hepatotoxicity and also with intracranial hemorrhage (including fatalities) and bleeding episodes in patients with hemophilia. The drug has anticoagulant properties in vitro and in animal models that are potentiated by vitamin E. Tipranavir is more likely to cause elevation in lipids and triglycerides than other boosted PIs, possibly due to the higher dose of ritonavir with which it is administered. Tipranavir contains a sulfa moiety, and about 10% of treated patients report a transient rash. The current formulation contains a high amount of vitamin E; patients should not take supplements containing this vitamin.

Like ritonavir, tipranavir is a substrate, inhibitor, and inducer of CYP enzymes. Tipranavir/ritonavir reduces the concentrations (AUC) of all coadministered PIs by 44%–76% and should not be administered with any of these agents. This reflects the combined effect of the increased ritonavir dose, as well as tipranavir’s unique capacity amongst PIs to induce expression of the P-glycoprotein drug transporter.

Entry Inhibitors
The two drugs available in this class, enfuvirtide and maraviroc, have different mechanisms of action (see Figure 64–1). Enfuvirtide inhibits fusion of the viral and cell membranes mediated by gp41 and CD4 interactions. Maraviroc is a chemokine receptor antagonist and binds to the host cell CCR5 receptor to block binding of viral gp120 (Tilton and Doms, 2010).

Maraviroc
Maraviroc blocks the binding of the HIV outer envelope protein gp120 to the CCR5 chemokine receptor (Figure 64–7). Maraviroc is approved for use in HIV-infected adults who have baseline evidence of predominantly CCR5-tropic virus. The drug has no activity against viruses that are CXCR4-tropic or dual-tropic (Tilton and Doms, 2010). Maraviroc retains activity against viruses that have become resistant to antiretroviral agents of other classes because of its unique mechanism of action.

HIV can develop resistance to this drug through two distinct pathways. A patient starting maraviroc therapy with HIV that is predominantly CCR5-tropic may experience a shift in tropism to CXCR4- or dual/mixed tropism predominance. This is especially likely in patients harboring low-level but undetected CXCR4- or dual/mixed-tropic virus prior to initiation of maraviroc. Alternatively, HIV can retain its CCR5-tropic but gain resistance to the drug through specific mutations in the V3 loop of gp120 that allow virus binding in the presence of inhibitor (Kuritzkes, 2011).

ADME. Maraviroc is the only antiretroviral drug approved at three different starting doses, depending on concomitant medications. When combined with most CYP3A inhibitors, the starting dose is 150 mg twice daily; when combined with most CYP3A inducers, the starting dose is 600 mg twice daily; for other concomitant medications, the starting dose is 300 mg twice daily. Once-daily maraviroc has been studied, but is not FDA-approved. The oral bioavailability of maraviroc, 23%–33%, is dose dependent. Food decreases bioavailability, but there are no food requirements for drug administration.

Untoward Effects and Drug Interactions. Maraviroc is generally well tolerated, but can cause dose- and concentration-dependent orthostatic
Mechanisms of Action and Resistance. The amino acid sequence of enfuvirtide derives from the transmembrane gp41 region of HIV-1 that is involved in fusion of the virus membrane lipid bilayer with that of the host cell membrane. The peptide blocks the interaction between the N36 and C34 sequences of the gp41 glycoprotein by binding to a hydrophobic groove in the N36 coil. This prevents formation of a six-helix bundle critical for membrane fusion and viral entry into the host cell (Tilton and Doms, 2010). Enfuvirtide inhibits infection of CD4+ cells by free virus particles. Enfuvirtide retains activity against viruses that have become resistant to antiretroviral agents of other classes. HIV can develop resistance to this drug through specific mutations in the enfuvirtide-binding domain of gp41.

**ADME.** Enfuvirtide is the only approved antiretroviral drug that must be administered parenterally. The bioavailability of subcutaneous enfuvirtide is 84% compared with an intravenous dose. Pharmacokinetics of the subcutaneous drug are not affected by site of injection. The major route of elimination for enfuvirtide has not been determined. The mean elimination \( t_{1/2} \) of parenteral drug is 3.8 h, necessitating twice-daily administration, which may create adherence issues for the patient.

### Untoward Effects and Drug Interactions.

The most prominent adverse effects of enfuvirtide are injection-site reactions. Most patients (98%) develop local side effects, including pain, erythema, and induration at the site of injection; 80% of patients develop nodules or cysts. Use of enfuvirtide has been associated with a higher incidence of lymphadenopathy and pneumonia. Enfuvirtide is not known to alter the concentrations of any coadministered drugs.

### Integrase Inhibitors

**Overview**

Chromosomal integration is a defining characteristic of retrovirus life cycles and allows viral DNA to remain in the host cell nucleus for a prolonged period of inactivity or latency (Figure 64–1). Because human DNA is not known to undergo excision/reintegration, this process is an excellent target for selective antiviral intervention. The HIV integrase inhibitors prevent formation of covalent bonds between host and viral DNA—a process known as strand transfer—presumably by interfering with essential divalent cations in the enzyme’s catalytic core (see Figure 64–8). In clinical trials, HIV integrase inhibitors produce a more rapid decline in plasma viral RNA over the first 3–4 months of therapy than other antiretroviral agents and are generally better tolerated than comparator agents (Hicks and Gulick, 2009).

**Raltegravir**

Raltegravir blocks the catalytic activity of the HIV-encoded integrase, preventing integration of viral DNA into the host chromosome (Figure 64–8). Raltegravir has potent activity against both HIV-1 and HIV-2. Because of its unique mechanism of action, this agent retains activity against viruses that have become resistant to antiretroviral agents of other classes. Raltegravir is approved for use in HIV-infected adults and children more than 4 weeks of age. A 1200 mg once-daily oral formulation was recently approved, eliminating the need for twice-daily dosing.

**ADME.** Peak concentrations of raltegravir occur about 1 h after oral dosing. Elimination is biphasic, with an \( \alpha \)-phase \( t_{1/2} \) of about 1 h and a terminal \( \beta \)-phase \( t_{1/2} \) of about 12 h, with the \( \alpha \)-phase predominating. The pharmacokinetics of raltegravir are highly variable. Moderate- and high-fat meals...
increase raltegravir's AUC by as much as 2-fold; a low-fat meal decreases AUC modestly (46%); however, there are no food requirements for raltegravir administration. The drug is 83% protein bound in human plasma. Raltegravir is eliminated mainly via glucuronidation by UGT1A1 (Hicks and Gulick, 2009).

Untoward Effects and Drug Interactions. Raltegravir generally is well tolerated, with little clinical toxicity. The most common complaints are headache, nausea, asthenia, and fatigue, which are also associated with coadministered NRTIs. Creatine kinase elevations, myopathy, and rhabdomyolysis have been reported, as has exacerbation of depression, but their relationship to raltegravir use is not clear (Hicks and Gulick, 2009). Raltegravir is rarely associated with DRESS (Ripamonti et al., 2014).

As a UGT1A1 substrate, raltegravir is susceptible to pharmacokinetic drug interactions involving inhibitors or inducers of this enzyme. Atazanavir, a moderate UGT1A1 inhibitor, increases the raltegravir AUC (41%–72%). Tenofovir increases the raltegravir AUC by 49%, but the mechanism for this interaction is unknown. When raltegravir is combined with the CYP inducer rifampin, the raltegravir dose should be doubled to 800 mg twice daily. Raltegravir has little effect on the pharmacokinetics of the usual coadministered drugs. Because the mechanism of action of HIV integrase strand transfer inhibitors involves chelation with a divalent cation (Mg²⁺) in the enzyme active site, chelation of divalent cations may occur in the GI tract following oral administration. It is therefore necessary to give magnesium- or aluminum-containing antacids and sulfasalazine 6 h before or 2 h after raltegravir administration. Administration of calcium and iron-containing supplements should also be separated from raltegravir by at least 2 h.

Elvitegravir

Elvitegravir blocks the catalytic activity of the HIV-encoded integrase, preventing integration of viral DNA into the host chromosome for both HIV-1 and HIV-2. Elvitegravir retains activity against viruses that have become resistant to antiretroviral agents of other classes, but shares cross-resistance with mutations affecting the HIV integrase inhibitor raltegravir (Johnson and Saravolatz, 2014). Elvitegravir is available only in single-tablet, once-daily coformulations with cobicistat, emtricitabine, and tenofovir disoproxil fumarate (STRIBILD) or tenofovir alafenamide (GENVoya). These coformulations are approved for use in HIV-infected adults and children more than 12 years of age.

A Note on Cobicistat. Cobicistat selectively inhibits CYP3A4 with potency similar to that of ritonavir but without anti-HIV activity (Sherman et al., 2015). Additional potential advantages compared to ritonavir include greater specificity for CYP 3A4, better tolerability, reduced impact on plasma lipids, and lack of P450 enzyme induction. However, cobicistat can inhibit some drug transport proteins and blocks the tubular transport of creatinine, resulting in a small but reversible increase in serum creatinine. Cobicistat is available only in coformulation with elvitegravir, atazanavir, or darunavir.

ADME. Peak concentrations of elvitegravir occur about 4 h after oral dosing. The plasma t₁/₂ of elvitegravir (administered as stribild) is approximately 13 h. Because light or high-fat meals increase the AUC of elvitegravir by 34% or 87%, respectively, elvitegravir coformulations should be given with food. The drug is largely (98%–99%) protein bound in human plasma. Unlike raltegravir and doluvetgravir, elvitegravir is eliminated mainly by CYP 3A4, thus explaining the substantial pharmacokinetic benefit of combining it with cobicistat. Elvitegravir coformulations should not be given to patients with baseline estimated creatinine clearance below 70 mL/min (for stribild) or 30 mL/min (for genvoya) because of potential effects on the NRTI components of the tablet (Johnson and Saravolatz, 2014).

Untoward Effects and Drug Interactions. Like other HIV integrase inhibitors, elvitegravir is well tolerated. In clinical trials, the only side effects reported in more than 10% of elvitegravir recipients were nausea and diarrhea; fewer than 1% of patients discontinued treatment due to adverse drug effects.

Although elvitegravir by itself is not likely to cause clinically significant drug-drug interactions, the impact of the coformulations with other drugs is dominated by the effects of cobicistat, which is a potent inhibitor of CYP 3A4 and a weak inhibitor of CYP 2D6. Caution is warranted in administering elvitegravir coformulations with other CYP 3A4 substrates with low therapeutic indices or with CYP 3A4 inducers that could lower concentrations of cobicistat or elvitegravir. This includes rifampins and St. John's wort. As with raltegravir, elvitegravir coformulations are subject to similar restrictions for coadministration of oral divalent cations (Mg²⁺, Al³⁺, Ca²⁺, Fe³⁺). Because tenofovir plus emtricitabine is effective suppressive therapy for chronic HBV infection (see Chapter 63), these coformulations may be used in patients coinfected with HIV-HBV, but they should not be discontinued abruptly because of the risk of rebound HBV replication and acute liver damage.

Dolutegravir

Dolutegravir blocks the catalytic activity of the HIV-encoded integrase of HIV-1 and HIV-2, preventing integration of viral DNA into the host chromosome. Dolutegravir retains activity against viruses that have become resistant to antiretroviral agents of other classes and also remains active against some viruses that are resistant to raltegravir or elvitegravir. Dolutegravir is approved for use in HIV-infected adults and children more than 12 years of age and weighing at least 40 kg. Dolutegravir is also available as a single-tablet, once-daily coformulation with abacavir and lamivudine. Given its high efficacy, tolerability, and convenience, dolutegravir is increasingly popular as a starting agent in

**Future Treatment Guidelines**

Several expert panels issue periodic recommendations for use of antiretroviral drugs for treatment-naïve and treatment-experienced adults and children. In the U.S., the Panel on Clinical Practices for Treatment of HIV Infection issues updated guidelines approximately every 6 months; their most recent guidelines can be accessed online (http://www.aidsinfo.nih.gov/Guidelines) (Department of Health and Human Services, 2016).

Treatment recommendations compare various regimens currently available for treatment-naïve patients and also address when to change therapy in individuals who are failing their current regimen. The specific drugs recommended may change as new choices become available and clinical research data accumulate. Selection of drugs in the developed world will be driven by genotypic and phenotypic resistance testing. However, future treatment guidelines will likely continue to be driven by three principles:

- Use of combination therapy to prevent the emergence of resistant virus
- Emphasis on regimen convenience, tolerability, and adherence in order to chronically suppress HIV replication
- Realization of the need for lifelong treatment under most circumstances

Treatment guidelines are not sufficient to dictate all aspects of patient management. Prescribers of antiretroviral therapy must maintain a comprehensive and current fund of knowledge regarding this disease and its pharmacotherapy. Because the treatment of HIV infection is a long-lived and complex affair, and because mistakes can have dire and irreversible consequences for the patient, the prescribing of these drugs should be limited to those with specialized training. Prescribers should also be aware that several additional antiretroviral agents are in advanced clinical development and could alter treatment possibilities. These include the NNRTI doravirine and the integrase strand transfer inhibitor (InSTI), cabegravir and bictegravir (Flexner and Saag, 2013). Experimentally, cabegravir has been formulated in nanoparticles having a 1/2 of 3 weeks, raising the possibility of a sustained-release formulation that would deliver the drug for several months.

**Acknowledgment:** Stephen P. Raffanti and David W. Haas contributed to this chapter in an earlier edition of this book. We have retained some of their text in the current edition.

Cancer pharmacology has changed dramatically during the recent past with the improved understanding of cancer biology and an ever-expanding set of newly developed drugs that target vulnerabilities in individual cancers. Effective early treatments have been developed for some fatal malignancies, including testicular cancer, lymphomas, and leukemia. Also, adjuvant chemotherapy and hormonal therapy can extend overall survival and prevent disease recurrence following surgical resection of localized breast, colorectal, and lung cancers. Chemotherapy is also employed as part of the multimodal treatment of locally advanced head and neck, breast, lung, and esophageal cancers; soft-tissue sarcomas; and pediatric solid tumors, thereby allowing for surgery that is more limited with favorable outcomes (Chabner and Roberts, 2005). In the past 5 years, the ability to harness the power of the immune system in the treatment of cancer has brought about a paradigm shift whereby some of the most feared diseases, such as melanoma and lung cancer and even late-stage metastatic disease, can be eradicated. For some cancers, response rates are surprisingly high: 87% in Hodgkin lymphoma even in heavily pretreated patients (Ansell et al., 2015), and 50% in patients with metastatic melanoma treated with combinations of PD-1 and CTLA4 immune checkpoint antibodies. Immune checkpoint inhibitors are currently approved for the treatment of bladder cancer, Hodgkin lymphoma, kidney cancer, lung cancer, and melanoma; more approvals are anticipated in the near future based on several hundred ongoing clinical trials.

Despite these major therapeutic successes, few categories of medication have a narrower therapeutic index and greater potential for causing harmful effects than anticancer drugs. A thorough understanding of their mechanisms of action, including clinical pharmacokinetics, drug interactions, and adverse effects, is essential for their safe and effective use. Anticancer drugs are quite varied in structure and mechanism of action. The group includes alkylating agents; antimetabolite analogues of folic acid, pyrimidine, and purine; natural products; hormones and hormone antagonists; and a variety of small-molecule drugs and antibodies directed at specific molecular targets, such as extracellular receptors, intracellular kinases, or the checkpoints of immune surveillance. Figure 65–1 depicts the cellular targets of these drugs, and Chapters 66–68 provide information on the different classes of drugs.

Anticancer drugs are increasingly used in a variety of nonmalignant diseases and have become treatment standards, for example, for autoimmune diseases (rituximab); rheumatoid arthritis (methotrexate and cyclophosphamide); Crohn disease (6-mercaptopurine); organ transplantation (methotrexate and azathioprine); sickle cell anemia (hydroxyurea); psoriasis (methotrexate); and wet macular degeneration (ranibizumab and aflibercept).

The Cell Cycle

An understanding of the cell cycle is essential for the rational use of anticancer drugs (Figure 65–2). Many cytotoxic agents act by damaging DNA. Their toxicity is greatest during S phase, the DNA synthetic phase of the cell cycle. Other agents, such as the vinca alkaloids and taxanes, block the formation of a functional mitotic spindle in the M phase. These agents are most effective on cells entering mitosis, the most vulnerable phase of the cell cycle. Accordingly, human cancers most susceptible to chemotherapy are those having a high percentage of proliferating cells. Normal tissues that proliferate rapidly (bone marrow, hair follicles, and intestinal epithelium) are thus also susceptible to damage from cytotoxic drugs. Slowly growing tumors with a small growth fraction (e.g., carcinomas of the colon or NSCLC) are less responsive to cell cycle-specific drugs.

Although cells from different tumors display differences in the duration of their transit through the cell cycle and in the fraction of cells in active proliferation, all cells display a similar pattern of cell cycle progression (Figure 65–2):

- A phase that precedes DNA synthesis (G1)
- A DNA synthesis phase (S)
- An interval following the termination of DNA synthesis (G2)
- The mitotic phase (M) in which the cell, containing a double complement of DNA, divides into two daughter G1 cells
- A probability of moving into a quiescent state (G0) and failing to move forward for long periods of time

At each transition point in the cell cycle, specific proteins, such as p53 and chk-1 and 2, monitor the integrity of DNA and, on detection of DNA damage, may initiate DNA repair processes or, in the presence of massive damage, direct cells down a pathway of cell death (apoptosis). Some anticancer drugs act at specific phases in the cell cycle, mainly at the S and M phases; other drugs are cytotoxic at any point in the cell cycle and are termed cell cycle phase nonspecific.

Each transition point in the cell cycle requires the activation of specific CDKs, which, in their active forms, couple with corresponding regulatory proteins called cyclins. The proliferative impact of CDKs is, in turn, dampened by inhibitory proteins such as p16INK4A, a tumor suppressor named for its molecular mass (protein of 16 kDa) and inhibition of CDK4. Tumor cells often exhibit changes in cell cycle regulation that lead to relentless proliferation (e.g., mutations or loss of p16INK4A or of other inhibitory components of the so-called retinoblastoma pathway, enhanced cyclin or enhanced CDK activity).
The CDK family consists of over 20 serine/threonine protein kinases that have been amongst the first pathway targets pursued for the treatment of cancer. However, different tissue selectivities and distinct cell cycle–specific activity periods of the various CDKs provide a challenge for the development of CDK inhibitors. CDK4/6 have become attractive targets because they control cell cycle progression from the G1 to the S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation and inactivation of the retinoblastoma (Rb) protein, followed by the transcription of factors that control transition into the S phase. CDK4/6 inhibition will thus cause a G1 arrest in susceptible cells that utilize this pathway. The CDK4/6 inhibitor palbociclib was recently approved for the treatment of breast cancer (see Chapter 67).

Because of the central importance of DNA to the identity and functionality of a cell, elaborate mechanisms (‘cell cycle checkpoints’) have evolved to monitor DNA integrity. If a cell possesses normal checkpoint function, drug-induced DNA damage will activate apoptosis when the cell reaches the G1/S or G2/M boundary. However, if the p53 gene product or other checkpoint proteins are mutated or absent or the checkpoint function fails, damaged cells will not divert to the apoptotic pathway but will proceed through the S phase and mitosis. The cell progeny will then emerge as a mutated and potentially drug-resistant subpopulation (see Figure 65–3A).

Cancer Evolution and Drug Discovery

The rapidly expanding knowledge of cancer biology and the ability to analyze cancer genome alterations in thousands of patient samples have led to a better understanding of the molecular evolution of cancer and the discovery of cancer-specific drug targets: growth factor receptors, intracellular signaling pathways, epigenetic processes, tumor vascularity, DNA repair defects, cell death pathways, and immune escape mechanisms (Hanahan and Weinberg, 2011). Human malignancies are a highly diverse

---

**Abbreviations**

ABL: Abelson murine leukemia viral oncogene homolog
ALK: anaplastic lymphoma kinase
ALL: acute lymphoblastic leukemia
ATRA: all-trans retinoic acid
BCR: breakpoint cluster region
BRAF: B-Raf proto-oncogene ser/thr protein kinase
CAR(T): chimeric antigen receptor T cell
CDK: cyclin-dependent kinase
ctDNA: cell-free mutant tumor DNA
CTLA4: cytotoxic T lymphocyte–associated protein 4
EGF(R): epidermal growth factor (receptor) [HER1, ErbB-1]
ER: estrogen receptor
FDA: Food and Drug Administration
GI: gastrointestinal
HER1: human EGFR (ErbB-1)
HER2: receptor tyrosine-protein kinase erbB-2
MEK: mitogen-activated protein kinase kinase
MHC: major histocompatibility class (protein)
NCCN: National Comprehensive Cancer Network
NSCLC: non–small cell lung cancer
PARP: poly(ADP-ribose) polymerase
PD-1: programed cell death 1
PD-L1: programed cell death 1 ligand 1
PR: progesterone receptor
RAR: retinoic acid receptor
VEGF: vascular endothelial growth factor
Adeno, adenocarcinoma; SCC, squamous cell carcinoma; SCLC, small cell lung cancer.

The dynamic evolution of individual cancer genomes and the implications for the development of therapies was established from the analyses of specimens from diverse cancers (Yates and Campbell, 2012). This dynamic was exemplified in a detailed analysis of a series of multiple parallel biopsies from different sites in patients with metastatic melanoma during treatment with inhibitors of BRAF. The genomic analysis of the biopsies revealed complex and distinct evolutionary branching architectures due to the selection of drug-resistant subpopulations during treatment (Shi et al., 2014).

Nevertheless, in many tumors, proliferation and survival of the majority of subpopulations depends on a shared (ancestral) constitutive activity of a single growth factor pathway, or so-called oncogene addiction. Inhibition of that pathway leads to cell death of the sensitive populations. Thus, imatinib attacks the unique and specific bcr-abl translocation in chronic myelocytic leukemia. Imatinib also inhibits c-kit and produces extended control of GI stromal tumors that express a mutated and constitutively activated form of c-kit. Monoclonal antibodies effectively inhibit tumor-associated antigens such as the amplified HER2 receptor in breast cancer cells (Slamon et al., 2001). Protein kinase inhibitors targeting mutant EGFR or mutant ALK in lung cancers improve disease outcomes over the use of conventional chemotherapy.

These examples emphasize that new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology. One response to the oncogene addiction paradigm has been to group cancers by shared vulnerabilities and include patients in so-called basket trials that evaluate a drug based on its target rather than particular disease entities and consider sensitivity and resistance to treatments in that context.

However, in the foreseeable future, targeted drugs and cytotoxics will continue to be used in combination. For instance, cytotoxics in combination with monoclonal antibodies such as trastuzumab or bevacizumab improve efficacy. At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better antinausea

Clinically detectable cancer lesions represent approximately 1 g of tumor tissue or 10^6 cells and can contain a multitude of subpopulations and a wide variety of genetic alterations (see legend of Figure 65–3). The dynamic evolution of individual cancer genomes and the implications for the development of therapies was established from the analyses of specimens from diverse cancers (Yates and Campbell, 2012). This dynamic was exemplified in a detailed analysis of a series of multiple parallel biopsies from different sites in patients with metastatic melanoma during treatment with inhibitors of BRAF. The genomic analysis of the biopsies revealed complex and distinct evolutionary branching architectures due to the selection of drug-resistant subpopulations during treatment (Shi et al., 2014).

Nevertheless, in many tumors, proliferation and survival of the majority of subpopulations depends on a shared (ancestral) constitutive activity of a single growth factor pathway, or so-called oncogene addiction. Inhibition of that pathway leads to cell death of the sensitive populations. Thus, imatinib attacks the unique and specific bcr-abl translocation in chronic myelocytic leukemia. Imatinib also inhibits c-kit and produces extended control of GI stromal tumors that express a mutated and constitutively activated form of c-kit. Monoclonal antibodies effectively inhibit tumor-associated antigens such as the amplified HER2 receptor in breast cancer cells (Slamon et al., 2001). Protein kinase inhibitors targeting mutant EGFR or mutant ALK in lung cancers improve disease outcomes over the use of conventional chemotherapy.

These examples emphasize that new strategies for drug discovery and development, and advances in patient care, will result from new knowledge of cancer biology. One response to the oncogene addiction paradigm has been to group cancers by shared vulnerabilities and include patients in so-called basket trials that evaluate a drug based on its target rather than particular disease entities and consider sensitivity and resistance to treatments in that context.

However, in the foreseeable future, targeted drugs and cytotoxics will continue to be used in combination. For instance, cytotoxics in combination with monoclonal antibodies such as trastuzumab or bevacizumab improve efficacy. At the same time, the toxicities of cytotoxic drugs have become more manageable with the development of better antinausea

Figure 65–3. Evolution of treatment resistance; mutational load of human cancers. A. Treatment resistance. Cancer cell subpopulations are selected based on their growth capacity, adaptation to the tumor microenvironment at the primary or metastatic site, and the evasion of immune surveillance. Drug treatment will add evolutionary pressure and select for resistant subpopulations. Differently colored dots indicate tumor subpopulations of different genetic makeup. B. Mutational load. Data are median number of somatic mutations per million bases plus or minus the range observed for some major human cancers. Note that the ordinate is a logarithmic scale. In 7042 cancer specimens between 100 and 1,000,000 mutations were detected per tumor specimen, with a 30- to 1000-fold range amongst individual specimens from a single cancer type (see original data in Alexandrov et al., 2013). A typical mutation burden of 10 somatic mutations per megabase (= 30,000 per genome of 3 × 10^9 base pairs) results in approximately 150 mutations in amino acid sequences that can alter protein function, drug sensitivity, and antigenicity. Such data have been analyzed in terms of the likelihood of formation of specific neoantigens that permit the immune system to distinguish between tumor and normal cells and are putative factors of importance in cancer immunotherapy (Schumacher and Schreiber, 2013). Adeno, adenocarcinoma; SCC, squamous cell carcinoma; SCLC, small cell lung cancer.
medications (see Chapter 50) and with granulocyte colony-stimulating factor to restore bone marrow function (see Chapters 41 and 67).

Finally, targeted drugs are helping to overcome resistance to chemo-therapeutic agents by normalizing blood flow, promoting apoptosis, and inhibiting prosurvival signals from growth factor pathways. Tumor angiogenesis leads to increased interstitial pressure and diminishes delivery of drugs to tumor cells; inhibitors of angiogenesis (e.g., bevacizumab) normalize blood flow and interstitial pressure, improve drug delivery, and can thus synergize with cytotoxic drugs in the treatment of lung, colon, and other cancers. It is also thought that the combination of cytotoxic drugs or pathway inhibitors can induce tumor cell death and antigen release and thus enhance responses to immune checkpoint inhibitors or other immune modulators. This concept is part of a new strategy for the treatment of patients with melanoma (Kauffmann et al., 2013) and should be relevant for a range of other cancers (Sharma and Allison, 2015). The ongoing development of activating and inhibitory drugs for additional immune checkpoint pathways (Anderson et al., 2016) will provide new options for drug combinations. One challenge in immunotherapy is the highly variable responses of the immune systems of individual patients that govern the success of the treatment.

**Drug Resistance**

Resistance remains the major obstacle to successful cancer treatment. Resistance results from a variety of molecular changes that can defeat the best-designed treatments. Mechanisms of drug resistance include poor drug absorption and delivery; genetically determined variability in drug transport, activation, and clearance; and mutations, amplifications, or deletions in drug targets (Holohan et al., 2013). The resistance process is best understood for pathway-targeted drugs. Tumors developing resistance to bcr-abl inhibitors and to inhibitors of the EGFR typically express mutations in the target enzyme. Cells exhibiting drug-resistant mutations preexist in a patient's tumor prior to drug treatment and are selected by drug exposure (see Figure 65–3A). Resistance to inhibitors of the EGFR may also develop through expression of an alternative receptor, c-met, which bypasses EGFR blockade and stimulates proliferation (Engelman et al., 2007). Defects in recognition of DNA breaks and overexpression of specific repair enzymes may contribute to resistance to cytotoxic drugs, and a loss of apoptotic pathways can lead to resistance to both cytotoxic and pathway-targeted drugs.

Resistance to immune checkpoint inhibitory drugs appears to follow patterns that are distinct from those of other anticancer drugs, as evidenced by their efficacy in many heavily pretreated patients. Combinations of therapies with pathway-targeted drugs as well as cytotoxic agents need to be evaluated to design effective combinations (Hughes et al., 2016). Finally, T cells carrying chimeric antigen receptors (CARs) can be directed against cancer cells that express specific antigens. CARs are engineered to contain an antigen recognition domain of a monoclonal antibody in the extracellular portion and intracellular signaling domains capable of activating T cells independently of the physiological pathway of antigen presentation by an MHC molecule (see Figures 67–3, 33–2, and 35–4). CD19-targeted T cells reached a 70%–90% response rate in patients with previously treated, relapsed B-cell leukemias (Khalil et al., 2016), indicating a lack of cross-resistance with conventional therapies. This result is consistent with the requirement for effective combination therapies, that is, complementary mechanisms of action and no overlap in major toxicities.

### Molecular Testing to Select Appropriate Drugs

Clinical trials and patient treatments increasingly employ results from biomarker analysis to identify patients likely to benefit from particular treatments and individuals at the greatest risk of toxicity. Some of the tests have been approved by the FDA as "companion diagnostics" in conjunction with specific drug therapies (see Table 65–1). Pretreatment testing of tumor specimens is standard practice in selecting patients for antihormonal therapy of breast cancer and for treatment with antibodies such as trastuzumab (anti-HER2). Detection of a mutated KRAS gene indicates that the tumor of a patient with colorectal cancer will not respond to anti-EGFR antibodies; in patients with lung cancers and EGFR mutations, treatment with erlotinib, gefitinib, or afatinib results in response rates of 70%, and in patients with ALK translocations, the response rates are similar for treatment with the ALK inhibitors crizotinib and ceritinib. A T790M "gatekeeper" mutation in EGFR (Kobayashi et al., 2005) accounts for about 60% of acquired resistance to first- and second-generation inhibitors but is sensitive to osimertinib, a third-generation EGFR inhibitor (Thomas et al., 2015). Overall, introduction of molecular analysis and appropriate choice of pathway-targeted inhibitors in the treatment of NSCLC has increased median survival of patients from less than 1 year to about 3 years.

†Also detectable as circulating tumor DNA (ctDNA) in blood samples.
Inherited differences in protein sequence polymorphisms or levels of RNA expression can also influence toxicity and antitumor response. For example, tandem repeats in the promoter region of the gene encoding thymidylate synthase, the target of 5-fluorouracil, determine the level of expression of the enzyme. Increased numbers of repeats are associated with increased gene expression, a lower incidence of toxicity, and a decreased rate of response in patients with colorectal cancer (Pullarkat et al., 2001). Polymorphisms of the dihydropyrimidine dehydrogenase gene, the product of which is responsible for degradation of 5-fluorouracil, are associated with decreased enzyme activity and a significant risk of overwhelming drug toxicity, particularly in the rare individual homozygous for the polymorphic genes (Van Kuilenburg et al., 2002).

Gene expression profiling, in which the levels of messenger RNA from thousands of genes are surveyed using gene arrays, has revealed tumor profiles that are highly associated with poor outcomes and warrant adjuvant chemotherapy (Sotiriou and Pusztai, 2009). As an alternative to this broad analysis, small sets of informative genes can be identified and used clinically. One example is a set of 21 genes used in the analysis of samples from patients with early stage breast cancer. Based on the known association between the expression pattern of the 21 genes and disease outcomes, the analysis of patient samples can predict the risk of disease relapse. Thus, one can identify the patients at a high risk who will benefit from adjuvant chemotherapy (Paik et al., 2004).

**Molecular Analysis and Tumor Heterogeneity**

One of the caveats to conclusions drawn from the molecular analysis of tumor specimens is the dynamic evolution of cancers outlined previously (see Figure 65–3). Clinically important mutations in subclones may be missed due to geographically inadequate sampling and may provide the wrong guidance to treatment decisions. Response to treatment of different subpopulations presents a further challenge and would require multiple-site, longitudinal sampling (Shi et al., 2014).

**Liquid Biopsies**

More recent technology advances have made it possible to measure circulating, ctDNA in blood samples from patients with cancer (“liquid biopsies”) and to follow changes in the abundance of mutant KRAS during colon cancer treatment (Diehl et al., 2008). The analysis of ctDNA has also shown that during aromatase therapy of breast cancer the appearance of mutant estrogen receptor coincides with subsequent resistance to aromatase inhibitor treatment (Schiavon et al., 2015). Furthermore, mutant KRAS DNA in the circulation was increased during the treatment of patients with colon cancer with EGFR antibodies but surprisingly reverted to baseline values after cessation of the treatment. This observation demonstrates the dynamic evolution of cancer subpopulations during drug treatment (Siravegna et al., 2015). The FDA recently approved a test for the presence of mutant EGFR DNA in blood samples of patients with NSCLC to select candidates for treatment with erlotinib and thus circumvent the need for a tissue biopsy. The incorporation of liquid biopsies into future treatment monitoring could provide additional molecular insights into drug efficacy and the onset of resistance.

**Achieving Therapeutic Integration and Efficacy**

The clinical benefit of cytotoxic drugs has primarily been measured by radiological assessment of drug effects on tumor size. Pathway-targeted agents, however, may slow or halt tumor growth, so their effects may be measured in the assessment of time to disease progression; however, for some immune checkpoint inhibitors, tumor lesions may initially increase in size due to cytotoxic lymphocyte infiltration. Thus, one of the great challenges is to assess efficacy and adjust drug regimens to achieve a therapeutic but nontoxic outcome. Treatment of patients with cancer requires a skillful interdigitation of pharmacotherapy with other modalities of treatment (e.g., surgery and irradiation). Each treatment modality carries its own risks and benefits, with the potential for both antagonistic and synergistic interactions between modalities, particularly between drugs and irradiation.

Individual patient characteristics determine the choice of modalities. Not all patients can tolerate drugs, and not all drug regimens are appropriate for a given patient. Renal and hepatic function, bone marrow reserve, general performance status, and concurrent medical problems all come into consideration in making a therapeutic plan. Other less-quantifiable considerations, such as the natural history of the tumor, the patient’s willingness to undergo difficult and potentially dangerous treatments, and the patient’s physical and emotional tolerance for adverse effects enter the equation, with the goal of balancing the likely long-term gains and risks in the individual patient. In particular, the long-term adverse effects of cytotoxic drugs have been related to the induction of cellular senescence in different organs that can adversely affect organ function and the overall well-being of patients long after completion of the treatments (Childs et al., 2015). The choice of treatment regimen should take all of this into account. Finally, in terminally ill patients, the treatment choices must be weighed carefully; the maximal length and highest quality of life may be achieved with palliative care rather than standard chemotherapy (Temel et al., 2010).

**A Cautionary Note**

Although advances in drug discovery and molecular profiling of tumors offer great promise for improving the outcomes of cancer treatment, a final word of caution regarding all treatment regimen deserves emphasis: the pharmacokinetics and toxicities of cancer drugs vary amongst individuals. It is imperative to recognize toxicities early, to alter doses or discontinue offending medication to relieve symptoms and reduce risk, and to provide vigorous supportive care. Toxicities affecting the heart, lungs, nervous system, or kidneys may be irreversible if recognized late in their course, leading to permanent organ damage or death. Fortunately, such toxicities can be minimized by early recognition and by adherence to standardized protocols and to the guidelines for each drug’s use.

**A Note on Treatment Regimens**

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter and the three that follow presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides examples that illustrate the complexities of current therapeutic regimens for two cancers.

- Mitomycin
- Mitotane
- Trabectedin
- L-Asparaginase
- Hydroxyurea
- Retinoids
- Arsenic Trioxide
CHAPTER 66

CYTOTOXIC DRUGS

Abbreviations

ABC: ATP-binding cassette
ABVD: doxorubicin (adriamycin), bleomycin, vinblastine, dacarbazine
ADA: adenosine deaminase
ADME: absorption, distribution, metabolism, excretion
ALL: acute lymphoblastic leukemia
AML: acute myeloid leukemia; acute myelocytic leukemia
API: acute promyelocytic leukemia
Ara-C: cytarabine, cytosine arabinoside
Ara-U: ara-uridine
ARDS: acute respiratory distress syndrome
C/EBP: CCAAT/enhancer binding protein
CHOP: cyclophosphamide, doxorubicin (H), vincristine (O) and prednisone
CLcr: creatinine clearance
CLL: chronic lymphocytic leukemia
CML: chronic myelocytic leukemia; chronic myelogenous leukemia
CNT1: concentrative nucleoside transporter 1
CDK: cyclin-dependent kinase
C/EBP: CCAAT/enhancer binding protein
CHOP: cyclophosphamide, doxorubicin (H), vincristine (O) and prednisone
CLcr: creatinine clearance
CLL: chronic lymphocytic leukemia
CML: chronic myelocytic leukemia; chronic myelogenous leukemia
CNT1: concentrative nucleoside transporter 1
dCK: deoxycytidine kinase
dCTP: deoxycttidine 5′-triphosphate
DCC: dichlorodiphenyltrichloroethane
dFdC: 2′,2′-difluorodeoxycytidine, gemcitabine
5′-dFdU: 5′-deoxyfluorodeoxyuridine
dHFR: dihydrofotolate reductase
dNTP: deoxyxucleotide triphosphate
dPDP: dihydroxymidinedehydrogenase
dTMP/TTP: deoxynucleotide monophosphate/triphosphate
dUMP/dUMP: deoxyuridine monophosphate/fluro dUMP
ENT1: equilibrative nucleoside transporter 1
FdUMP: deoxynucleotide, fluorodeoxyuridine monophosphate
FH/Glu/FH/Glu; dihydro-/tetrahydrofolate polyglutamates
FOLFOX: FOLFOX plus irinotecan
FOLFOX: folinic acid, 5FU and oxaliplatin
5FU: 5-fluorouracil
FUdR: fluorodeoxyuridine
G-CSF: granulocyte colony-stimulating factor
GI: gastrointestinal
GSH: glutathione
GST: glutathione S-transferase
Hb: hemoglobin
HbF: fetal hemoglobin
HDAC: histone deacetylase
HDM-L: high-dose MTX with leucovorin rescue
HGPRT: hypoxanthine guanine phosphoribosyl transferase

HMG: high-mobility group
HMM: hexamethylmelamine
HSV: herpes simplex virus
SHT: serotonin, 5-hydroxytryptamine
HU: hydroxyurea
IMP: inosine monophosphate
JAK2: Janus kinase 2
MAO: monoamine oxidase
MDS: myelodysplastic syndrome
MESNA: 2-mercaptopentethane sulfonate
methyl-CCNU: semustine
MGMT: O′-alkyl, methylguanin methyltransferase
MLL: mixed-lineage leukemia
MM: multiple myeloma
MMR: mismatch repair
MOPP: nitrogen mustard, oncovin (vincristine), procarbazine, and prednisone
6MP: 6-mercaptopurine
MRP: multidrug resistance-associated protein
MSH6: mutator S homologue 6
MTA: metotrexet
MTIC: methyl-triazeno-imidazole-carboxamide
mTOR: mammalian target of rapamycin
MTX: methotrexate
Nab-paclitaxel: albumin-bound nanoparticle solution of paclitaxel
NCCN: National Comprehensive Cancer Network
NER: nucleotide excision repair
NHL: non-Hodgkin lymphoma
NSAID: nonsteroidal anti-inflammatory drug
PG: polyglutamate
Pgp: P-glycoprotein
PI3K: phosphoinositide 3-kinase
PML: promyelocytic leukemia
PN: peripheral neuropathy
PRP: 5-phosphoribosyl-1-pyrophosphate
PVC: procarbazine, vincristine and CCNU
RAR: retinoic acid receptor
RNR: ribonucleoside diphosphate reductase
ROS: reactive oxygen species
SBC: squamous cell carcinoma
SHMT: serine hydroxymethyltransferase
TEM: triethylenemelamine
TEPA: triethylenamphosphoramide
6TG: 6-thioguanine
THF: tetrahydrofolate
T-IMP: 6-thioguanosine-5′-monophosphate
6-thioGMP: 6-thioguanosine-5′-monophosphate
Thiotepa: triethylenemelamine
TMP: thymidine monophosphate
TPMT: thiopurine methyltransferase
TS: thymidylate synthase
TPP: thymidine triphosphate
VOD: veno-occlusive disease
XPG: xeroderma pigmentosum endonuclease G
PHARMACOTHERAPY OF NEOPLASTIC DISEASE

A Note on Treatment Regimens

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

1. Alkylating Agents and Platinum Coordination Complexes

HISTORY Alkylating Anticancer Drugs

The discovery and initial development of alkylating anticancer drugs are based on observations of the effects of chemical warfare in World War I (Chabner and Roberts, 2005). The pervasively toxic sulfur mustard gas that caused topical burns to skin, eyes, lungs, and mucosa also caused aplasia of the bone marrow and lymphoid tissue and ulceration of the GI tract (Krumbhaar, 1919). In 1942, Louis Goodman and Alfred Gilman, the originators of this text, demonstrated the activity of nitrogen mustards against mouse lymphoma. Their clinical studies of intravenous nitrogen mustards in patients with lymphoma launched the modern era of cancer chemotherapy (Gilman and Philips, 1946).

Actions Common to Alkylating Drugs

Six major types of alkylating agents are used in the chemotherapy of cancer: nitrogen mustards, ethyleneimines, alkyl sulfonates, nitrosoureas, triazines, and methylhydrazines. Because of similarities in their mechanisms of action and resistance, platinum complexes are also discussed with classical alkylating agents, even though they do not alkylate DNA but instead form covalent metal adducts with DNA.

The chemotherapeutic alkylating agents have in common the property of forming highly reactive carbonium ion intermediates. These reactive intermediates covalently link to sites of high electron density, such as phosphates, amines, sulphydryl, and hydroxyl groups. Their chemotherapeutic and cytotoxic effects are directly related to the alkylation of reactive amines, oxygen, or phosphates on DNA. The N7 atom of guanine is particularly susceptible to the formation of a covalent bond with bifunctional alkylating agents and may represent the key target that determines their biological effects (Figure 66–1). Other atoms in the purine and pyrimidine bases of DNA, including N1 and N3 of the adenine ring, N3 of cytosine, and O6 of guanine, react with these agents, as do the amino and sulphydryl groups of proteins and the sulphydryls of glutathione. The general mechanisms of alkylating agents on DNA are illustrated in Figure 66–1 using mechlorethamine (nitrogen mustard).

With the bifunctional alkylating agents such as nitrogen mustard and its derivatives that are used therapeutically (Figure 66–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or a nucleic acid to a protein.

Figure 66–1 Mechanism of action of alkylating agents of mechlorethamine, a prototypic nitrogen mustard. A. Activation reaction. B. Alkylation of N7 of guanine. With bifunctional drugs such as nitrogen mustards (see Figure 66–2), the second 2-chloroethyl side chain can undergo a similar activation cross-link of two nucleic acid chains or a nucleic acid to a protein.

Figure 66–2 Nitrogen mustards employed in therapy.

SECTION VIII PHARMACOTHERAPY OF NEOPLASTIC DISEASE
Structure-Activity Relationships

Although alkylating agents share the capacity to alkylate biologically important molecules, modification of the basic backbone structure changes reactivity, lipophilicity, active transport across biological membranes, sites of macromolecular attack, and mechanisms of DNA repair, all of which determine drug activity in vivo. For several of the most valuable agents (e.g., cyclophosphamide, ifosfamide), the active alkylating moieties are generated in vivo through hepatic metabolism (Figure 66–3).

The newest (2008) approved alkylating agent, bendamustine, has the typical chloroethylnitrosourea structure in nitrogen mustard (M) attached to a benzimidazole backbone. The unique properties and activity of this drug may derive from this purine-like structure; the agent produces slowly repaired DNA cross-links, lacks cross-resistance with other classical alkylators (Leoni et al., 2008), and is approved for treatment of CLL and large-cell lymphomas refractory to standard alkylators.

Figure 66–3 Activation and metabolism of cyclophosphamide. Cyclophosphamide is activated (hydroxylated) by CYP2B, with subsequent transport of the activated intermediate to sites of action. The selectivity of cyclophosphamide against certain malignant tissues may result in part from the capacity of normal tissues to degrade the activated intermediates via aldehyde dehydrogenase, glutathione transferase, and other pathways. Ifosfamide is structurally similar to cyclophosphamide (see Figure 66–2); whereas cyclophosphamide has two chloroethyl groups on the oxazaphosphorine ring, ifosfamide has one 2-chloroethyl group of ifosfamide is on the cyclic phosphoramidate nitrogen of the oxazaphosphorine ring. Ifosfamide is activated by hepatic CYP3A4 and proceeds more slowly than activation of cyclophosphamide, with greater production of dechlorinated metabolites and chloroacetaldehyde. These differences in metabolism likely account for the higher doses of ifosfamide required for equitoxic effects, the greater neurotoxicity of ifosfamide, and perhaps differences in the antitumor spectra of cyclophosphamide and ifosfamide.

Esters of alkane sulfonic acids alkylate DNA through the release of methyl radicals. Busulfan is of value in high-dose chemotherapy.

General Pharmacological Actions

Cytotoxic Actions

The capacity of alkylating agents to interfere with DNA integrity and function and to induce cell death in rapidly proliferating tissues provides the basis for their therapeutic and toxic properties. Acute effects manifest primarily against rapidly proliferating tissues; however, certain alkylating agents may have damaging effects on tissues with normally low mitotic indices (e.g., liver, kidney, and mature lymphocytes); effects in these tissues usually are delayed. Lethality of DNA alkylation depends on the recognition of the adduct, the creation of DNA strand breaks by repair enzymes, and an intact apoptotic response. In nondividing cells, DNA damage activates a checkpoint that depends on the presence of a normal p53 gene. Cells thus blocked in the G1/S interface either repair DNA alkylation or undergo apoptosis. Malignant cells with mutant or absent p53 fail to suspend cell-cycle progression, do not undergo apoptosis, and can exhibit resistance to these drugs.
Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, and produce a prolonged and cumulative myelosuppression lasting months and, to a lesser extent, intestinal mucosa. Most alkylating agents (i.e., melphalan, chlorambucil, cyclophosphamide, and ifosfamide) cause myelosuppression, with a nadir of the peripheral blood granulocyte count at 6–10 days and recovery in 14–21 days. Cyclophosphamide has lesser effects on peripheral blood platelet counts than do the other agents. Busulfan suppresses all blood elements, particularly stem cells, and may produce a prolonged and cumulative myelosuppression lasting months or even years. For this reason, it is used as a preparative regimen in allogeneic bone marrow transplantation. Carmustine and other chloroethyl-nitrosoureas cause delayed and prolonged suppression of both platelets and granulocytes, reaching a nadir 4–6 weeks after drug administration and reversing slowly thereafter. Both cellular and humoral immunity are suppressed by alkylating agents, which have, therefore, been used to treat various autoimmune diseases. Immunosuppression is reversible at usual doses, but opportunistic infections may occur with extended treatment.

Mucosa, Hair Follicles

Alkylating agents are highly toxic to dividing mucosal cells and to hair follicles, leading to oral mucosal ulceration, intestinal denudation, and alopecia. Mucosal effects are particularly damaging in high-dose chemotherapy protocols associated with bone marrow transplantation, as they predispose to bacterial sepsis arising from the GI tract. In these protocols,
Alkylating agents have a high capacity to induce leukemia. Acute non-lymphocytic leukemia, induced by treatment, is often associated with the nephrotic syndrome. Caution is advised when the drug is considered for nonneoplastic conditions, not only because of its toxic effects but also because of its potential for inducing premature menopause, sterility, teratogenic effects, and leukemia.

**Leukemogenesis**
Alkylating agents have a high capacity to induce leukemia. Acute non-lymphocytic leukemia, induced by treatment, is often associated with a higher incidence of p53 mutations, partial or total deletions of chromosome 5 or 7, and reduced response to chemotherapy. Incidence peaks about 4 years after therapy and may affect up to 5% of patients treated on regimens containing alkylating drugs. Leukemia often is preceded by a period of neutropenia or anemia and by bone marrow morphology consistent with myelodysplasia.

**Clinical Pharmacology of Nitrogen Mustards**

**Mechlorethamine**
Mechlorethamine HCl was the first clinically used nitrogen mustard and is the most reactive of the drugs in this class. It is used topically for treatment of CTCL, as a solution that is rapidly mixed and applied to affected areas. It has been largely replaced by cyclophosphamide, melphalan, and other more stable alkylating agents.

**Cyclophosphamide**

**ADME**
Cyclophosphamide is well-absorbed orally and is activated to the 4-hydroxy intermediate (see Figure 66–3). Its rate of metabolic activation exhibits significant interpatient variability and increases with successive doses in high-dose regimens but appears to be saturable at concentrations of the parent compound greater than 150 μM. 4-Hydroxy)cyclophosphamide may be oxidized further by aldehyde oxidase, either in liver or in tumor tissue, to inactive metabolites. 4-Hydroxy)cyclophosphamide and its tautomer, aldophosphamide, travel in the circulation to tumor cells, where aldophosphamide cleaves spontaneously, generating stoichiometric amounts of phosphoramide mustard and acrolein. Phosphoramide mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with cyclophosphamide.

Pretreatment with CYP inducers such as phenobarbital enhances the rate of activation of the azoxystrophanes but does not alter total exposure to active metabolites over time and does not affect toxicity or efficacy. Cyclophosphamide can be used in full doses in patients with renal dysfunction because it is eliminated by hepatic metabolism. Patients with significant hepatic dysfunction should receive reduced doses. Maximal plasma concentrations are achieved about 1 h after oral administration; the t 1/2 of parent drug in plasma is about 7 h.

**Therapeutic Uses**
Cyclophosphamide is administered orally or intravenously. Recommended doses vary widely, and standard protocols for determining the schedule and doses of cyclophosphamide in combination with other chemotherapeutic agents should be consulted. The neutrophil nadir of 500–1000 cells/mm 3 generally serves as a lower limit for dosage adjustments in prolonged therapy.

The clinical spectrum of activity for cyclophosphamide is broad. It is an essential component of many effective drug combinations for non-Hodgkin lymphomas, other lymphoid malignancies, breast and ovarian cancers, and solid tumors in children. Complete remissions and presumed cures have been reported when cyclophosphamide was given as a single agent for Burkitt lymphoma. It frequently is used in combination with doxorubicin and a taxane as adjuvant therapy after surgery for breast cancer. Because of its potent immunosuppressive properties, cyclophosphamide has been used to treat autoimmune disorders, including Wegener granulomatosis, rheumatoid arthritis, and the nephrotic syndrome. Caution is advised when the drug is considered for nonneoplastic conditions, not only because of its toxic effects but also because of its potential for inducing premature menopause, sterility, teratogenic effects, and leukemia.

**Adverse Effects**
Phosphoramide mustard is responsible for antitumor effects, while acrolein causes hemorrhagic cystitis often seen during therapy with
cyclophosphamide. Patients should receive vigorous intravenous hydration during high-dose treatment. Refractory bladder hemorrhage can become life-threatening and may require cystectomy for control of bleeding. Inappropriate secretion of antidiuretic hormone has been observed (usually at doses greater than 50 mg/kg) and can lead to water intoxication because these patients usually are vigorously hydrated. In addition to the cystitis (counteracted by MESNA and diuresis), GI, pulmonary, renal, hepatic, and cardiac toxicities (hemorrhagic myocardial necrosis) may occur after high-dose therapy with total doses greater than 200 mg/kg.

Ifosfamide

Ifosfamide is an analogue of cyclophosphamide. Severe urin ary tract and CNS toxicity initially limited the use of ifosfamide, but adequate hydration and coadministration of MESNA have reduced its bladder toxicity. CNS toxicity is handled with methylene blue.

ADME

Ifosfamide has a plasma elimination \( t_{1/2} \approx 1.5 \) h after doses of 3.8–5 g/m² and a somewhat shorter \( t_{1/2} \) at lower doses; its pharmacokinetics are highly variable due to variable rates of hepatic metabolism (see legend to Figure 66–3).

Therapeutic Uses

Ifosfamide is approved for treatment of patients with relapsed germ cell testicular cancer and is frequently used for first-time treatment of pediatric or adult patients with sarcomas. It is a common component of high-dose chemotherapy regimens with bone marrow or stem cell rescue. In nonmyeloablative regimens, ifosfamide is infused intravenously over at least 30 min at a dose of 1.2 g/m²/d or less for 5 days. Intravenous MESNA is given as bolus injections in a dose equal to 20% of the ifosfamide dose concomitantly and an additional 20% again 4 and 8 h later, for a total MESNA dose of 60% of the ifosfamide dose. Alternatively, MESNA may be given concomitantly in a single dose equal to the ifosfamide dose. Patients also should receive at least 2 L of oral or intravenous fluid daily. Treatment cycles are repeated every 3–4 weeks.

Adverse Effects

Ifosfamide has a similar toxicity profile as cyclophosphamide, although it causes greater platelet suppression, neurotoxicity, nephrotoxicity, and urothelial damage. In high-dose regimens (i.e., total doses of 12–14 g/m²), it may cause severe neurological toxicity, including hallucinations, coma, and death, with symptoms appearing 12 h to 7 days after beginning the ifosfamide infusion. This toxicity may result from a metabolite, chloroacetaldehyde. Ifosfamide also causes nausea, vomiting, anorexia, leukopenia, nephrotoxicity, and VOD of the liver.

Melphalan

The alkylating agent melphalan primarily is used to treat multiple myeloma and, less commonly, in high-dose chemotherapy with marrow transplantation. The general pharmacological and cytotoxic actions of melphalan are similar to those of other bifunctional alkylators. The drug is not a vesicant.

ADME

Oral melphalan is absorbed in an inconsistent manner and, for most indications, is given as an intravenous infusion. The drug has a \( t_{1/2} \) of about 45–90 min; 10%–15% of an administered dose is excreted unchanged in the urine. Patients with decreased renal function may develop unexpectedly severe myelosuppression.

Therapeutic Uses and Adverse Effects

Melphalan for multiple myeloma is administered orally for 4–7 days every 28 days, with dexamethasone or thalidomide. Treatment is repeated at 4-week intervals based on response and tolerance. Dosage adjustments should be based on blood cell counts. Melphalan also may be used in myeloablative regimens followed by bone marrow or peripheral blood stem cell reconstitution. The toxicity of melphalan is mostly hematological and is similar to that of other alkylating agents. Nausea and vomiting are less frequent. The drug causes less alopecia and, rarely, renal or hepatic dysfunction.

Chlorambucil

The cytotoxic effects of chlorambucil on the bone marrow, lymphoid organs, and epithelial tissues are similar to those observed with other nitrogen mustards. As an orally administered agent, chlorambucil is well tolerated in small daily doses and provides flexible titration of blood counts. Nausea and vomiting may result from single oral doses of 20 mg or greater.

ADME

Oral absorption of chlorambucil is adequate and reliable. The drug has a \( t_{1/2} \) in plasma of about 1.5 h and is hydrolyzed to inactive products.

Therapeutic Uses and Adverse Effects

Chlorambucil is almost exclusively used in treating CLL. In treating CLL, chlorambucil is given once daily and continued for 3–6 weeks. With a fall in the peripheral total leukocyte count or clinical improvement, the dosage is titrated to maintain neutrophils and platelets at acceptable levels. Maintenance therapy often is required to maintain clinical response. Chlorambucil treatment may continue for months or years, achieving its effects gradually and often without significant toxicity to a compromised bone marrow. Marked hypoplasia of the bone marrow may be induced with excessive doses, but the myelosuppressive effects are moderate, gradual, and rapidly reversible. GI discomfort, azoospermia, amenorrhea, pulmonary fibrosis, sei zures, dermatitis, and hepatotoxicity rarely may be encountered. A marked increase in the incidence of AML and other tumors has been noted in the treatment of polycythemia vera and in patients with breast cancer receiving chlorambucil as adjuvant chemotherapy.

Bendamustine

Bendamustine is approved for treatment of CLL and non-Hodgkin lymphoma. Bendamustine is given as a 30-min intravenous infusion on days 1 and 2 of a 28-day cycle. Lower doses may be indicated in heavily pre-treated patients. Bendamustine is rapidly degraded through sulfhydryl interaction and adduct formation with macromolecules; less than 5% of the parent drug is excreted in the urine intact. N-Demethylation and oxidation produce metabolites that have antitumor activity, but less than that of the parent molecule. The parent drug has a plasma \( t_{1/2} \) of about 30 min. The clinical toxicity pattern of bendamustine is typical of alkylators, with a rapidly reversible myelosuppression and mucositis, both generally tolerable.

Ethyleneimines and Methylmelamines

Although nitrogen mustards containing chloroethyl groups constitute the most widely used class of alkylating agents, other alkylators such as ethyleneimines with greater chemical stability and well-defined activity in specific types of cancer have value in clinical practice.

Altretamine

Altretamine is structurally similar to triethylene melamine (TEM). Its precise mechanism of cytotoxicity is unknown, although it can alkylate DNA and proteins. It is a palliative treatment of patients with persistent or recurrent ovarian cancer following cisplatin-based combination therapy. The usual dosage of altretamine as a single agent in ovarian cancer is 260 mg/m²/d in four divided doses, for 14 or 21 consecutive days out of a 28-day cycle, for up to 12 cycles.

ADME

Altretamine is well absorbed from the GI tract; its elimination \( t_{1/2} \) is 4–10 h. The drug undergoes rapid demethylation in the liver; the principal metabolites are pentamethylmelamine and tetramethyl melamine.
Adverse Effects
The main toxicities of altretamine are myelosuppression and neurotoxicity. Altretamine causes both peripheral and central neurotoxicity (ataxia, depression, confusion, drowsiness, hallucinations, dizziness, and vertigo). Neurological symptoms abate on discontinuation of therapy. Peripheral blood counts and a neurological examination should be performed prior to the initiation of each course of therapy. Therapy should be interrupted for at least 14 days and subsequently restarted at a lower dosage if the white cell count falls to less than 2000 cells/mm$^3$ or the platelet count falls to less than 75,000 cells/mm$^3$ or if neurotoxic or intolterable GI symptoms occur. If neurological symptoms fail to stabilize on the reduced-dose schedule, altretamine should be discontinued. Nausea and vomiting also are common side effects and may be dose limiting. Renal dysfunction may necessitate discontinuing the drug. Other rare adverse effects include rashes, alopecia, and hepatic toxicity. Severe, life-threatening orthostatic hypotension may develop in patients who receive MAO inhibitors, amitriptyline, imipramine, or phenelzine concurrently with altretamine.

Thiotepa
Thiotepa consists of three ethyleneimine groups stabilized by attachment to the nucleophilic thiophosphoryl base. Its current use is primarily for high-dose chemotherapy regimens. Hepatic CYPs rapidly convert thiotepa to its desulfurated primary metabolite, TEPA. Both thiotepa and TEPA form DNA cross-links.

ADME
Within hours of thiotepa administration, TEPA becomes the predominant form of the drug present in plasma. The parent compound has a plasma $t_{1/2}$ of 1.2–2 h; TEPA has a longer $t_{1/2}$ of 3–24 h. Thiotepa pharmacokinetics essentially are the same in children as in adults at conventional doses (≤80 mg/m$^2$/d for 3 days. Less than 10% of the administered drug appears in urine as the parent drug or the primary metabolite.

Adverse Effects
Toxicities include myelosuppression and, to a lesser extent, mucositis. Myelosuppression tends to develop somewhat later than with cyclophosphamide, with leukopenic nadirs at 2 weeks and platelet nadirs at 3 weeks. In high doses, thiotepa may cause neurotoxic symptoms, including coma and seizures.

Alkyl Sulfonates
Busulfan
Busulfan exerts few pharmacological actions other than myelosuppression at conventional doses and, prior to the advent of imatinib mesylate, was a standard agent for patients in the chronic phase of myelocytic leukemia and caused a severe and prolonged pancytopenia in some patients. Busulfan has a neutral pH and is well absorbed after oral administration and has a plasma $t_{1/2}$ of 2–3 h. The drug is conjugated to GSH by GSTA1A and further metabolized by CYP-dependent pathways; its major urinary metabolite is melphalan sulfonic acid. In high doses, children less than 18 years of age clear the drug two to four times faster than adults and tolerate higher doses. Busulfan clearance varies considerably amongst patients. VOD is associated with high AUC ($>1500$ μM × min) and slow clearance, leading to recommendations for dose adjustment based on drug-level monitoring.

A target steady-state concentration of 600–900 ng/mL in plasma in adults or AUC < 1000 μM × min in children achieves an appropriate balance between toxicity and therapeutic benefit.

Therapeutic Uses
In treating CML, the initial oral dose of busulfan varies with the total leukocyte count and the severity of the disease; daily doses are adjusted to subsequent hematological and clinical responses, with the aim of reducing the total leukocyte count to 10,000 cells/mm$^3$ or less. A decrease in the leukocyte count usually is not seen during the first 10–15 days of treatment, and the leukocyte count may actually increase during this period. Because the leukocyte count may fall for more than 1 month after discontinuing the drug, it is recommended that busulfan be withdrawn when the total leukocyte count has declined to about 15,000 cells/mm$^3$. A normal leukocyte count usually is achieved within 12–20 weeks. During remission, daily treatment resumes when the total leukocyte count reaches about 50,000 cells/mm$^3$.

In high-dose therapy, anticonvulsants must be used concomitantly to protect against acute CNS toxicities, including tonic-clonic seizures that may occur several hours after each dose. Although phenytoin is a frequent choice, phenytoin induces the GSTs that metabolize busulfan, reducing its AUC by about 20%. In patients requiring concomitant antiseizure medication, non–enzyme-inducing benzodiazepines such as lorazepam and clonazepam are recommended as an alternative to phenytoin. If phenytoin is used concurrently, plasma busulfan levels should be monitored and the busulfan dose adjusted accordingly.

Adverse Effects
The toxic effects of busulfan are related to its myelosuppressive properties; prolonged thrombocytopenia may occur. Occasionally, patients experience nausea, vomiting, and diarrhea. Long-term use leads to impotence, sterility, amenorrhea, and fetal malformation. Rarely, patients develop asthenia and hypotension. High-dose busulfan causes VOD of the liver in 10% or fewer of patients, as well as seizures, hemorrhagic cystitis, permanent alopecia, and cataracts. The coincidence of VOD and hepatotoxicity is increased by its coadministration with drugs that inhibit CYPs, including imidazoles and metronidazole, possibly through inhibition of the clearance of busulfan or its toxic metabolites.

Nitrosoureas
The nitrosoureas have an important role in the treatment of brain tumors and find occasional use in treating lymphomas and in high-dose regimens with bone marrow reconstitution. They function as bifunctional alkylating agents but differ from conventional nitrogen mustards in both pharmacological and toxicological properties.

Carmustine (BCNU) and lomustine (CCNU, not discussed in detail) are highly lipophilic and thus readily cross the blood-brain barrier, an important property in the treatment of brain tumors. Unfortunately, with the exception of streptozocin, nitrosoureas cause profound and delayed myelosuppression, with recovery 4–6 weeks after a single dose. Long-term treatment with the nitrosoureas, especially semustine (methyl-CCNU), has resulted in renal failure. As with other alkylating agents, the nitrosoureas are highly carcinogenic and mutagenic. They generate both alkylating and carbamylation moieties (see Figure 66–4).

Carmustine (BCNU)
Carmustine's major action is its alkylation of DNA at the O6-guanine position, an adduct repairable by MGMT. Methylation of the MGMT promoter inhibits its expression in about 30% of primary gliomas and is associated with sensitivity to nitrosoureas. In high doses with bone marrow rescue, carmustine produces hepatic VOD, pulmonary fibrosis, renal failure, and secondary leukemia.

ADME
Carmustine is unstable in aqueous solution and in body fluids. After intravenous infusion, it disappears from the plasma with a highly variable $t_{1/2}$ of 15–90 min or more. Approximately 30%–80% of the drug appears in the urine within 24 h as degradation products. The alkylating metabolites
enter rapidly into the CSF, and their concentrations in the CSF reach 15%–30% of the concurrent plasma values.

**Therapeutic Uses**

Carmustine (BCNU) is administered intravenously over 1–2 h and repeated every 6 weeks. Because of its ability to cross the blood-brain barrier, carmustine has been used in the treatment of malignant gliomas. An implantable carmustine wafer is available for use as an adjunct to surgery for recurrent glioblastoma multiforme.

**Streptozocin**

Streptozocin (or streptozotocin) has a methylnitrosourea moiety attached to the 2-carbon of glucose. It has a high affinity for cells of the islets of Langerhans and causes diabetes in experimental animals.

**ADME**

Streptozocin is rapidly degraded following intravenous administration. The $t_{1/2}$ of the drug is about 15 min. Only 10%–20% of a dose is recovered intact in the urine.

**Therapeutic Uses**

Streptozocin is used in the treatment of human pancreatic islet cell carcinoma and carcinoid tumors. It is administered intravenously once daily for 5 days; this course is repeated every 6 weeks. Alternatively, a higher dose can be given weekly for 2 weeks, and the weekly dose then can be increased as tolerated.

**Adverse Effects**

Nausea is frequent. Mild, reversible renal or hepatic toxicity occurs in approximately two-thirds of cases; in fewer than 10% of patients, renal toxicity may be cumulative with each dose and may lead to irreversible renal failure. Streptozocin should not be given with other nephrotoxic drugs. Hematological toxicities (anemia, leukopenia, thrombocytopenia) occur in 20% of patients.

**Triazenes**

**Dacarbazine (DTIC)**

Dacarbazine functions as a methylating agent after metabolic activation to the monomethyl triazeno metabolite MTIC. It kills cells in all phases of the cell cycle. Resistance has been ascribed to the removal of methyl groups from the O6-guanine bases in DNA by MGMT.

**ADME**

Dacarbazine is administered intravenously. After an initial rapid phase ($t_{1/2}$ of about 20 min), dacarbazine is cleared from plasma with a terminal $t_{1/2}$ of about 5 h. The $t_{1/2}$ is prolonged in the presence of hepatic or renal disease. Almost 50% of the compound is excreted intact in the urine by tubular secretion.

**Therapeutic Uses**

The primary clinical indication for dacarbazine is in the chemotherapy of Hodgkin disease. In combination with other drugs for Hodgkin disease, dacarbazine is given on day 1 and 15 and repeated every 4 weeks for up to 6 cycles (see NCCN). It is modestly effective against malignant melanoma and adult sarcomas. Dacarbazine for malignant melanoma is given for a 10-day period, repeated every 28 days; alternatively, it can be given daily for 5 days and repeated every 3 weeks. Extravasation of the drug may cause tissue damage and severe pain. Its use in patients with melanoma has largely been replaced by immune checkpoint inhibitors and agents targeting the typically activated mitogen-active protein kinase pathway (see Chapter 67).

**Adverse Effects**

Dacarbazine induces nausea and vomiting in more than 90% of patients; vomiting usually develops 1–3 h after treatment and may last up to 12 h. Myelosuppression, with both leukopenia and thrombocytopenia, is mild and readily reversible within 1–2 weeks. A flu-like syndrome may occur. Hepatotoxicity, alopecia, facial flushing, neurotoxicity, and dermatological reactions are less common adverse effects.

**Temozolomide**

Temozolomide is the standard agent, in combination with radiation therapy, for patients with malignant glioma and astrocytoma. Temozolomide, like dacarbazine, forms the methylating metabolite MTIC and kills cells in all phases of the cell cycle. It is more active in MGMT deficient tumors.

**ADME**

Temozolomide is administered orally and has a bioavailability approaching 100%. Plasma levels of the parent drug decline with a $t_{1/2}$ of 1–2 h. The primary active metabolite MTIC reaches a maximum plasma concentration (150 ng/mL) 90 min after a dose and declines with a $t_{1/2}$ of 2 h. Little intact drug is recovered in the urine, the primary urinary metabolite being the inactive imidazole carboxamide.

**Adverse Effects**

The toxicities of temozolomide mirror those of DTIC. Hematological monitoring is necessary to guide dosing adjustments.

**Methylhydrazines**

**Procarbazine**

Procarbazine is used in malignant brain tumors and in combination regimens for patients with Hodgkin disease.

**Mechanisms of Action**

The antineoplastic activity of procarbazine results from its conversion by CYP-mediated hepatic oxidative metabolism to highly reactive alkylating species that methylate DNA. Activated procarbazine can produce chromosomal damage, including chromatid breaks and translocations, consistent with its mutagenic and carcinogenic actions. Resistance to procarbazine develops rapidly when it is used as a single agent; one mechanism of resistance results from increased expression of MGMT, which repairs methylation of guanine.

**ADME**

The pharmacokinetic behavior of procarbazine has not been thoroughly defined. The drug is extensively metabolized by CYPs to azo, methyldiazoxo, and benzylazoxo intermediates, which are found in the plasma and yield the alkylating metabolites in tumor cells. In patients with brain cancer, the concurrent use of antiseizure drugs that induce hepatic CYPs does not significantly alter the pharmacokinetics of the parent drug.

**Therapeutic Uses**

Procarbazine is used in combination regimens such as MOPP for Hodgkin disease. It is also used in treating gliomas as part of the PVC (procarbazine, vincristine and CCNU) regimen.

**Adverse Effects**

The most common toxic effects include leukopenia and thrombocytopenia, which begin during the second week of therapy and reverse within 2 weeks off treatment. GI symptoms such as mild nausea and vomiting occur in most patients; diarrhea and rash are noted in 5%–10% of cases. Behavioral disturbances also have been reported. Because procarbazine augments sedative effects, the concomitant use of CNS depressants should be avoided. The drug is a weak MAO inhibitor; it blocks the metabolism of catecholamines, sympathomimetics, and dietary tyramine and thus may provoke hypertension in patients concurrently exposed to these. Procarbazine has disulfiram-like actions; therefore, the ingestion of alcohol should be avoided. The drug is highly carcinogenic, mutagenic, and teratogenic and is associated with a 5%–10% risk of acute leukemia in patients treated with MOPP. The highest risk is for patients who also receive radiation therapy. Procarbazine is a potent immunosuppressive agent. It causes infertility, particularly in males.
Platinum Coordination Complexes

Platinum coordination complexes have broad antineoplastic activity and have become the foundation for treatment of ovarian, head and neck, bladder, esophagus, lung, and colon cancers. Although cisplatin and other platinum complexes do not form carbonium ion intermediates like other alkylating agents or formally alkylate DNA, they covalently bind to nucleophilic sites on DNA and share many pharmacological attributes with alkylators.

Mechanisms of Action

Cisplatin, carboplatin, and oxaliplatin enter cells by the high-affinity Cu" transporter CTR1 (SLC31A1, a member of the solute carrier family; see Chapter 5) and in doing so contribute to the degradation of the transporter. The compounds are actively extruded from cells by ATP7A and ATP7B copper exporters and by MRP1; variable expression of these transporters may contribute to clinical resistance, along with a variety of other proteins and epigenetic phenomena (Shen et al., 2012). Inside the cell, the chloride, cyclohexane, or oxalate ligands of the analogues are displaced by water molecules, yielding a positively charged molecule that reacts with nucleophilic sites on DNA and proteins.

Aquation of cisplatin is favored at the low concentrations of Cl⁻ inside the cell and in the urine. High concentrations of Cl⁻ stabilize the drug, explaining the effectiveness of Cl⁻ diuresis in preventing nephrotoxicity. The activated platinum complexes can react with electron-rich regions, such as sulfhydryls, and with various sites on DNA, forming both intrastrand and interstrand cross-links. The DNA-platinum adducts inhibit replication and transcription, lead to single- and double-stranded breaks and miscoding, and if recognized by p53 and other checkpoint proteins, cause induction of apoptosis. Adduct formation is an important predictor of clinical response (Reed et al., 1998). The analogues differ in the conformation of their adducts and the effects of adduct on DNA structure and function. Oxaliplatin and carboplatin are slower to form adducts. The oxaliplatin adducts are bulkier and the effects of adduct on DNA structure and function. Oxaliplatin and carboplatin are slower to form adducts. The oxaliplatin adducts are bulkier and the effects of adduct on DNA structure and function.

Resistance to Platinum Analouges

Resistance to the platinum analogues likely is multifactorial; the compounds differ in their degree of cross-resistance. Carboplatin shares cross-resistance with cisplatin in most experimental tumors, while oxaliplatin does not.

A number of factors influence sensitivity to platinum analogues in experimental cells, including intracellular drug accumulation and intracellular levels of glutathione and other sulphydryls, such as metallothionein, that bind to and inactivate the drug and rates of repair of DNA adducts. Repair of platinum-DNA adducts requires participation of the NER pathway. Inhibition or loss of NER increases sensitivity to cisplatin in patients with ovarian cancer, while overexpression of NER components is associated with poor response to cisplatin- or oxaliplatin-based therapy in lung, colon, and gastric cancer (Paré et al., 2008).

Resistance to cisplatin, but not oxaliplatin, appears to be partly mediated through loss of function in the MMR proteins. In the absence of effective repair of DNA-platinum adducts, sensitive cells cannot replicate or transcribe affected portions of the DNA strand. Some DNA polymerases can bypass adducts, possibly contributing to resistance. Overexpression of copper efflux transporters ATP7A and ATP7B correlates with poor survival after cisplatin-based therapy for ovarian cancer (Shen et al., 2012).

Cisplatin

ADME

Cisplatin is given only intravenously. To prevent renal toxicity, it is important to establish a chloride diuresis by the infusion of 1–2 L of normal saline prior to treatment. The appropriate amount of cisplatin then is diluted in a solution containing dextrose, saline, and mannitol and administered intravenously over 4–6 h. Because aluminum inactivates cisplatin, the drug should not come in contact with needles or other infusion equipment that contain aluminum during its preparation or administration. After intravenous administration, cisplatin has an initial plasma elimination 1/2 of 25–50 min; concentrations of total (bound and unbound) drug fall thereafter, with a 1/2 of 24 h or more. More than 90% of the platinum in the blood is covalently bound to plasma proteins. High concentrations of cisplatin are found in the kidney, liver, intestine, and testes; cisplatin penetrates poorly into the CNS. Only a small portion of the drug is excreted by the kidney during the first 6 h; by 24 h, up to 25% is excreted, and by 5 days, up to 43% of the administered dose is recovered in the urine, mostly covalently bound to protein and peptides. Biliary or intestinal excretion of cisplatin is minimal.

Therapeutic Uses

Cisplatin, in combination with bleomycin, etoposide, or with ifosfamide and vinblastine, cures 90% of patients with testicular cancer. Used with paclitaxel, cisplatin or carboplatin induces complete response in the majority of patients with carcinoma of the ovary. Cisplatin produces responses in cancers of the bladder, head and neck, cervix, and endometrium; all forms of carcinoma of the lung; anal and rectal carcinomas; and neoplasms of childhood. The drug also sensitizes cells to radiation therapy and enhances control of locally advanced lung, esophageal, and head and neck tumors when given with irradiation.

Adverse Effects

Cisplatin-induced nephrotoxicity has been largely ameliorated by forced pretreatment hydration and chloride diuresis. Amifostine, a thiophosphate cytoprotective agent, reduces renal toxicity associated with repeated administration of cisplatin. Ototoxicity caused by cisplatin is unaffected by diuresis and is manifested by tinnitus and high-frequency hearing loss. Marked nausea and vomiting occur in almost all patients and usually can be controlled with 5HT receptor antagonists, neurokinin (NK) receptor antagonists (e.g., aprepitant), and high-dose corticosteroids.

At higher doses or after multiple cycles of treatment, cisplatin causes a progressive peripheral motor and sensory neuropathy that may worsen after discontinuation of the drug and may be aggravated by subsequent or simultaneous treatment with taxanes or other neurotoxic drugs. Cisplatin causes mild-to-moderate myelosuppression, with transient...
leukopenia and thrombocytopenia. Anemia may become prominent after multiple cycles of treatment. Electrolyte disturbances, including hypomagnesemia, hypocalcemia, hypokalemia, and hypophosphatemia, are common. Hypocalcemia and hypomagnesemia secondary to tubular damage and renal electrolyte wasting may produce tetany if untreated. Routine measurement of Mg$^{2+}$ concentrations in plasma is recommended. Hyperuricemia, hemolytic anemia, and cardiac abnormalities are rare side effects. Anaphylactic-like reactions, characterized by facial edema, bronchospasm, tachycardia, and hypotension, may occur within minutes after administration and should be treated by intravenous injection of epinephrine and with corticosteroids or antihistamines. Cisplatin has been associated with the development of cisplatin nephrotoxicity months to years after administration. Omission of cisplatin may cause acute and asymptomatic AML, usually 4 years or more after treatment.

**Carboplatin**

The mechanisms of action and resistance and the spectrum of clinical activity of carboplatin are similar to cisplatin. However, the two drugs differ significantly in their chemical, pharmacokinetic, and toxicological properties.

**ADME**

Because carboplatin is much less reactive than cisplatin, the majority of drug in plasma remains in its parent form, unbound to proteins. Most drug is eliminated via renal excretion, with a $t_{1/2}$ of about 2 h. A small fraction of platinum binds irreversibly to plasma proteins and disappears slowly, with a $t_{1/2}$ of 5 days or more.

**Therapeutic Uses**

Carboplatin and cisplatin are equally effective in the treatment of patients with suboptimally debulked ovarian cancer, non–small cell lung cancer, and extensive-stage small cell lung cancer; however, carboplatin may be less effective than cisplatin in the treatment of patients with germ cell, head and neck, and esophageal cancers. Carboplatin is an effective alternative for responsive tumors in patients unable to tolerate cisplatin because of impaired renal function, refractory nausea, significant hearing impairment, or neuropathy, but doses must be adjusted for renal function. In addition, it may be used in high-dose therapy with bone marrow or peripheral stem cell rescue. Carboplatin is administered as an intravenous infusion over at least 15 min and is given once every 21–28 days; the overall dose of carboplatin should be adjusted in proportion to the reduction in creatinine clearance for patients with CL$\text{cr}$ < 60 mL/min and use the Calvert formula for adjustment (Calvert et al., 1989).

**Adverse Effects**

Carboplatin is relatively well tolerated clinically, causing less nausea, neurotoxicity, ototoxicity, and nephrotoxicity than cisplatin. The dose-limiting toxicity of carboplatin is myelosuppression, primarily thrombocytopenia. It may cause a hypersensitivity reaction; in patients with a mild reaction, premedication, graded doses of drug, and more prolonged infusion lead to desensitization.

**Oxaliplatin**

**ADME**

Oxaliplatin has a short $t_{1/2}$ in plasma, probably as a result of its rapid uptake by tissues and its reactivity; the initial $t_{1/2}$ is about 17 min. No dose adjustment is required for hepatic dysfunction or for patients with a CL$\text{cr}$ $\geq$ 20 mL/min.

**Therapeutic Uses**

Oxaliplatin exhibits a range of antitumor activity (colorectal and gastric cancer) that differs from other platinum agents. Oxaliplatin's effectiveness in colorectal cancer is perhaps due to its MMR- and HMG-independent effects. It also suppresses expression of TS, the target enzyme of 5FU. In combination with 5FU, it is approved for treatment of patients with colorectal cancer.

**Adverse Effects**

The dose-limiting toxicity of oxaliplatin is peripheral neuropathy. An acute form, often triggered by exposure to cold liquids, manifests as paresthesias or dysesthesias in the upper and lower extremities, mouth, and throat. A second type relates to cumulative dose and has features similar to cisplatin neuropathy; 75% of patients receiving a cumulative dose of 1560 mg/m$^2$ experience some progressive sensory neurotoxicity, with dysesthesias, ataxia, and numbness of the extremities. Hematological toxicity is mild to moderate, except for rare immune-mediated cytopenias; nausea is well controlled with SHT receptor antagonists. Oxaliplatin may cause leukemia and pulmonary fibrosis months to years after administration. Oxaliplatin may cause an acute allergic response with urticaria, hypotension, and bronchoconstriction.

**II. Antimetabolites**

**Folic Acid Analogues**

Folic acid is an essential dietary factor that is converted by enzymatic reduction to FH$_4$, cofactors that provide methyl groups for the synthesis of precursors of DNA (thymidylate and purines) and RNA (purines) (Wilson et al., 2014). Folic acid analogues such as MTX interfere with FH$_4$ metabolism (Figure 66–5), reducing the cellular capacity for one-carbon transfer and methylation reactions in the synthesis of purine ribonucleotides and TMP, thereby inhibiting DNA replication.

**HISTORY Antifolate Chemotherapy**

Antifolate chemotherapy produced the first striking, although temporary, remissions in leukemia (Farber et al., 1948) and the first cure of a solid tumor, choriocarcinoma (Berlin et al., 1963). Interest in folate antagonists further increased with the development of curative combination therapy for childhood acute lymphocytic leukemia; in this therapy, MTX played a critical role in both systemic treatment and intrathecal therapy. Introduction of high-dose regimens with "rescue" of host toxicity by the reduced folate leucovorin (folinic acid, citrovorum factor, 5-formyl tetrahydrofolate, N$^{5}$-formyl FH$_4$) further extended the effectiveness of this drug to both systemic and CNS lymphomas, osteogenic sarcoma, and leukemias. Recognition that MTX, an inhibitor of DHFR, also directly inhibits the folate-dependent enzymes of de novo purine synthesis and thymidylate synthesis led to development of antifolate analogues that specifically target these other folate-dependent enzymes. New congeners have greater capacity for transport into tumor cells (prolatrexate) and exert their primary inhibitory effect on TS (raltixetrex), early steps in purine biosynthesis (lometrexol), or both (the multitargeted antifolate pemetrexed).

**Mechanism of Action**

The primary target of folic analogs, such as MTX, is the enzyme DHFR (see Figure 66–6). To function as a cofactor in one-carbon transfer reactions, folate must be reduced to FH$_4$, inhibitors such as MTX, with a high affinity for DHFR (Kd about 0.01–0.2 nM), cause partial depletion of N$^{5}$-10 methylene FH$_4$ and N$^{10}$formyl FH$_4$, cofactors that are required for the synthesis of thymidylate and purines. In addition, MTX, like cellular folates, undergoes addition of a series of polyglutamates (MTX-PGs) in both normal and tumor cells (Figure 66–5). These PGs constitute intracellular storage forms of folates and folate analogues that dramatically increase inhibitory potency of the analogue for additional sites, including TS and two early enzymes in the purine biosynthetic pathway. The FH$_4$ PGs that accumulate in cells behind the blocked DHFR reaction also act as inhibitors of TS and other enzymes (see Figure 66–6) (Allegra et al., 1987b).
Selective Toxicity: Rescue
As with most antimetabolites, MTX is only partially selective for tumor cells and kills rapidly dividing normal cells, such as those of the intestinal epithelium and bone marrow. Folate antagonists kill cells during the S phase of the cell cycle and are most effective when cells are proliferating rapidly. The toxic effects of MTX may be terminated by administering leucovorin, a fully reduced folate coenzyme that repletes the intracellular pool of FH₄ cofactors (see Figure 66–6).

Cellular Entry and Retention
Because folic acid and many of its analogues are polar, they cross the blood-brain barrier poorly and require specific transport mechanisms to enter mammalian cells. Three inward folate transport systems are found on mammalian cells:

1. A folate receptor, which has high affinity for folic acid but much lower ability to transport MTX and other analogues
2. The reduced folate transporter, the major transit protein for MTX, raltitrexed, pemetrexed, and most analogues
3. A transporter that is active at low pH

The reduced folate transporter is highly expressed in the hyperdiploid subtype of ALL, which has extreme sensitivity to MTX (Pui et al., 2004). Once in the cell, additional glutamyl residues are added to the molecule by the enzyme folypolyglutamate synthetase. Because these higher PGs are strongly charged and cross cellular membranes poorly, polyglutamation serves as a mechanism of ion trapping within the cell. The polyglutamation may also account for the prolonged retention of MTX in choriocarcinoma epithelium (where it is a potent abortifacient); in tumors derived from this tissue, such as choriocarcinoma cells; and in normal tissues subject to cumulative drug toxicity, such as liver. Polyglutamyl folates and analogues have substantially greater affinity than the monoglutamate form for folate-dependent enzymes that are required for purine and thymidylate synthesis and have at least equal affinity for DHFR.

Newer Congeners
New folate antagonists that are better substrates for the reduced folate carrier have been identified. In efforts to bypass the obligatory membrane transport system and to facilitate penetration of the blood-brain barrier, lipid-soluble folate antagonists also have been synthesized. Trimetrexate, a lipid-soluble analogue that lacks a terminal glutamate, has modest...
Mechanisms of Resistance to Antifolates

Resistance to MTX can involve alterations in each known step in MTX action, including:

- Impaired transport of MTX into cells
- Production of altered forms of DHFR that have decreased affinity for the inhibitor
- Increased concentrations of intracellular DHFR through gene amplification or altered gene regulation
- Decreased ability to synthesize MTX-PG's
- Increased expression of a drug efflux transporter of the MRP class (see Chapter 5)

The DHFR levels in leukemia cells increase within 24 h after treatment of patients with MTX, probably as a result of induction of DHFR synthesis. Unbound DHFR protein may bind to its own message and attenuate its own translation, while the DHFR-MTX complex is ineffective in blocking DHFR translation. With longer periods of drug exposure, tumor cell populations emerge that contain markedly increased levels of DHFR. These cells contain multiple gene copies of DHFR either in mitotically unstable double-minute chromosomes (extrachromosomal elements) or in stably integrated, homogeneously staining chromosomal regions or ampiclons (Schimke et al., 1978). Similar gene amplification target proteins have been implicated in the resistance to other antitumor agents, including 5FU, cisplatin, and pentostatin (2′-deoxycoformycin) and observed in patients with lung cancer (Curt et al., 1985).

High doses of MTX may permit entry of the drug into transport-defective cells and may permit the intracellular accumulation of MTX in concentrations that inactivate high levels of DHFR. The understanding of resistance to pemetrexed is incomplete. In various cell lines, resistance seems to arise from loss of influx transport, TF amplification, changes in purine biosynthetic pathways, or loss of polyglutamation.

ADME

Methotrexate is readily absorbed from the GI tract at doses of less than 25 mg/m²; larger doses are absorbed incompletely and are routinely administered intravenously. After intravenous administration, the drug disappears from plasma in a triphasic fashion. The rapid distribution phase is followed by a second phase, which reflects renal clearance (t1/2 of about 2–3 h). A third phase has a t1/2 of about 8–10 h. This terminal phase of disappearance, if prolonged by renal failure, may be responsible for major toxic effects of the drug on the bone marrow, GI epithelium, and skin. Distribution of MTX into body spaces, such as the pleural or peri-toneal cavity, occurs slowly. However, if such spaces are expanded (e.g., by ascites or pleural effusion), they may act as a site of storage and slow release of the drug, resulting in prolonged elevation of plasma concentrations and more severe bone marrow toxicity.

Approximately 50% of MTX binds to plasma proteins and may be displaced from plasma albumin by myriad drugs, including sulfonamides, salicylates, tetracycline, chloramphenicol, and phenytoin; caution should be used if these drugs are given concomitantly. Up to 90% of a given dose of MTX is excreted unchanged in the urine, mostly within the first 8–12 h. Metabolism of MTX usually is minimal. After high doses, however, metabolites are readily detectable; these include 7-hydroxy-MTX, which is potentially nephrotoxic. Renal excretion of MTX occurs through a combination of glomerular filtration and active tubular secretion. Therefore, the concurrent use of drugs that reduce renal blood flow (e.g., NSAIDs), that are nephrotoxic (e.g., cisplatin), or that are weak organic acids (e.g., aspirin) can delay drug excretion and lead to severe myelosuppression. In patients with renal insufficiency, the dose should be adjusted in proportion to decreases in renal function, and high-dose regimens should be avoided. Concentrations of MTX in CSF are only 3% of those in the systemic circulation at steady state; hence, neoplastic cells in the CNS probably are not killed by standard dosage regimens. When high doses of MTX are given, cytotoxic concentrations of MTX reach the CNS beyond the blood-brain barrier. MTX is retained in the form of PGs for long periods (e.g., weeks in the kidneys, several months in the liver).

Pharmacogenetics may influence the response to antifolates and their toxicity. The C677T substitution in methylenetetrahydrofolate reductase reduces the activity of the enzyme that generates N5,N10 methylene FH4, the cofactor for TS, and thereby increases MTX toxicity (Pullarkat et al., 2001). The presence of this polymorphism in leukemic cells confers increased sensitivity to MTX and might also modulate the toxicity and therapeutic effect of pemetrexed, a predominant TS inhibitor. Likewise, polymorphisms in the promoter region of TS affect its expression and, by altering the intracellular levels of TS, modulate the response and toxicity of both antifolates and fluoropyrimidines (Pui et al., 2004).

Therapeutic Uses

Methotrexate is a critical drug in the management of childhood ALL. High-dose MTX is of great value in remission induction and consolidation and in the maintenance of remissions in this highly curable disease. A 6- to 24-h infusion of relatively large doses of MTX may be employed every 2–4 weeks but only when leucovorin rescue follows within 24 h of the MTX infusion. For maintenance therapy, it is administered at a lower dose, orally every week. Outcome of treatment in children correlates inversely with the rate of drug clearance. During MTX infusion, high steady-state levels are associated with a lower leukemia relapse rate. Methotrexate is of limited value in adults with AML, except for treatment and prevention of leukemic meningitis.

The intrathecal administration of MTX has been employed for treatment or prophylaxis of meningeal leukemia or lymphoma and for treatment of meningeal carcinomatosis. This route of administration achieves high concentrations of MTX in the CSF and also is effective in patients whose systemic disease has become resistant to MTX. The treatment is repeated every 4 days until malignant cells no longer are evident in the CSF. Leucovorin may be administered to counteract the potential toxicity of MTX that escapes into the systemic circulation, although this generally is not necessary. Because MTX administered into the lumbar space distributes poorly over the cerebral convexities, the drug may be given via an intraventricular catheter system in the treatment of active intracerebral disease. MTX is of established value in choriocarcinoma and related throphoblastic tumors of women; cure is achieved in about 75% of advanced cases treated sequentially with MTX and dactinomycin and in more than 90% when early diagnosis is made. For choriocarcinoma, MTX is administered intramuscularly every other day for four doses, alternating with leucovorin. Courses are repeated at 3-week intervals, toxicity permitting, and urinary β-human chorionic gonadotropin titers are used as a guide for persistence of disease.

Beneficial effects also are observed in the combination therapy of Burkitt and other non-Hodgkin lymphomas. MTX is a component of regimens for carcinomas of the breast, head and neck, ovary, and bladder. HDM-L is a standard agent for adjuvant therapy of osteosarcoma and produces a high complete response rate in CNS lymphomas. The administration
of HDM-L has the potential for renal toxicity, probably related to the precipitation of the drug, a weak acid, in the acidic tubular fluid. Thus, vigorous hydration and alkalinization of urine pH are required prior to drug administration. If MTX values measured 48 h after drug administration are 1 μM or higher, higher doses (100 mg/m²) of leucovorin must be given until the plasma concentration of MTX falls to less than 50 nM. With appropriate hydration and urine alkalinization, and in patients with normal renal function, the incidence of nephrotoxicity following HDM-L is less than 2%. In patients who become oliguric, intermittent hemodialysis is ineffective in reducing MTX levels. Continuous-flow hemodialysis can eliminate MTX at about 50% of the clearance rate in patients with intact renal function. Alternatively, a MTX-cleaning enzyme, glucarpidase, is FDA approved for the treatment of MTX toxicity. Glucarpidase is a recombinant bacterial carboxypeptidase G2 that converts MTX into glutamate and 2,4-diamino-N(10)-methylpyrroic acid. These metabolites are less toxic and are excreted by the liver. MTX concentrations in plasma fall by 99% or more within 5–15 min following enzyme administration. However, systemically administered carboxypeptidase G2 has little effect on MTX levels in the CSF.

Methotrexate is used in the treatment of severe, disabling psoriasis (see Chapter 70) orally for 5 days, followed by a rest period of at least 2 days, or intravenously weekly. It also is used at low dosage to induce remission in refractory rheumatoid arthritis. MTX inhibits cell-mediated immune reactions and is employed to suppress graft-versus-host disease in allogenic bone marrow and organ transplantation and for the treatment of dermatomyositis, Wegener granulomatosis, and Crohn disease (see Chapters 38 and 51). MTX is also used as an abortifacient, generally in combination with a prostaglandin (see Chapter 44).

Adverse Effects

The primary toxicities of antifolates are on the bone marrow and the intestinal epithelium. Patients may be at risk for spontaneous hemorrhage or life-threatening infection and may require prophylactic transfusion of platelets and broad-spectrum antibiotics if febrile. Side effects usually reverse completely within 2 weeks, but prolonged myelosuppression may occur in patients with compromised renal function who have delayed drug excretion. The dosage of MTX (and likely pemetrexed) must be reduced in proportion to any reduction in creatinine clearance. Additional toxicities of MTX include alopecia, dermatitis, an allergic interstitial pneumonitis, nephrotoxicity (after high-dose therapy), defective oogenesis or spermatogenesis, abortion, and teratogenesis. Low-dose MTX may lead to cirrhosis after long-term continuous treatment, as in patients with psoriasis. Intrathecal administration of MTX often causes meningeal and an inflammatory response in the CSF. Seizures, coma, and death may occur rarely. Note that leucovorin does not reverse neurotoxicity.

Pemetrexed toxicity mirrors that of MTX, with the additional feature of a prominent erythematous and pruritic rash in 40% of patients. Dexamethasone, 4 mg twice daily on days 1, 0, and +1, markedly diminishes this toxicity. Unpredictably severe myelosuppression with pemetrexed, seen especially in patients with preexisting homocystinemia, largely is eliminated by concurrent administration of low dosages of folic acid, 350–1000 mg/d, beginning 1–2 weeks prior to pemetrexed and continuing while the drug is administered. Patients should receive intramuscular vitamin B₁₂ (1 mg) with the first dose of pemetrexed to correct possible B₁₂ deficiency. These small doses of folate and B₁₂ do not compromise the therapeutic effect.

Pyrimidine Anallogues

The pyrimidine antimetabolites encompass a diverse group of drugs that inhibit RNA and DNA function. The fluoropyrimidines and certain purine analogues (6MP and 6TG) inhibit the synthesis of essential precursors of DNA. Others, such as the cytidine and adenosine nucleoside analogues, become incorporated into DNA and block its further elongation and function (Wilson et al., 2014). Other inhibitory effects of these analogues may contribute to their cytotoxicity and their capacity to induce differentiation.

Cellular Actions of Pyrimidine Antimetabolites

Four bases (Figure 66–7) form DNA: two pyrimidines (thymine and cytosine) and two purines (guanine and adenine). RNA differs in that it incorporates uracil instead of thymine as one of its bases. Strategies for inhibiting DNA synthesis are based on the ability to create analogues of these precursors that readily enter tumor cells and become activated intracellularly. As an example, the pyrimidine analog 5FU is converted to an FDUMP, which in turn blocks TS, an enzyme required for the physiological conversion of dUMP to dTMP, a component of DNA (see Figure 66–6). Other analogues incorporate into DNA itself and thereby block its function (Wilson et al., 2014).

Cells can make the purine and pyrimidine bases de novo and convert them to their active triphosphates (dNTPs), providing substrates for DNA polymerase. Alternatively, cells can salvage free bases or their deoxynucleosides from the bloodstream. Thus, cells can take up uracil, guanine, and their analogues and convert them to (deoxy)nucleotides by the addition of deoxyribose and phosphate groups. Antitumor analogues of these bases (5FU, 6TG) can be formulated as simple substituted bases. Other bases, including cytosine, thymine, and adenine, and their analogues can only be used as deoxynucleosides, which are readily transported into cells and activated to deoxynucleotides by intracellular kinase. Thus, cytarabine (cytosine arabinoside; Ara-C), gemcitabine, 5-azacytidine, and adenosine analogues (cladribine) (Figures 66–7 and 66–8) are nucleosides readily taken up by cells, converted to nucleotides, and incorporated into DNA.

Fludarabine phosphate, a nucleotide, is dephosphorylated rapidly in plasma, releasing the nucleoside that is readily taken up by cells. Analogues may differ from the physiological bases in a variety of ways: by altering in the purine or pyrimidine ring; by altering the sugar attached...
Amplification of TS, mutation of TS to a form that is not inhibited by 5FU or FUdR has been ascribed to resistance to the cytotoxic effects of 5FU or FUdR.

**Mechanisms of Resistance**

Resistance to the cytotoxic effects of 5FU or FUdR has been ascribed to loss or decreased activity of the enzymes necessary for activation of 5FU, amplification of TS, mutation of TS to a form that is not inhibited by 5FU, and high levels of the degradative enzymes dihydouracil dehydrogenase and thymidine phosphorylase. TS levels are finely controlled by an autoregulatory feedback mechanism wherein the unbound enzyme interacts with and inhibits the translational efficiency of its own mRNA, which provides for the rapid TS modulation needed for cellular division. When TS is bound to FdUMP, inhibition of translation is relieved and levels of free TS rise, restoring thymidylate synthesis. Thus, TS autoregulation may be an important mechanism by which malignant cells become insensitive to the effects of 5FU.

**Combination With Leucovorin**

Some malignant cells appear to have insufficient concentrations of 5,10-methylene FH, and thus cannot form maximal levels of the inhibited ternary complex with TS. Addition of exogenous folate in the form of leucovorin increases formation of the complex and enhances responses to 5FU. A number of other agents have been combined with 5FU in attempts to enhance the cytotoxic activity through biochemical modulation. MTX, by inhibiting purine synthesis and increasing cellular pools of PRPP, enhances the activation of 5FU and increases antitumor activity of 5FU when given prior to but not following 5FU. The combination of cisplatin and 5FU has yielded impressive responses in tumors of the upper aerodigestive tract, but the molecular basis of their interaction is unclear. A combination with oxaliplatin, which downregulates TS expression, is commonly used with 5FU and leucovorin for treating patients with metastatic colorectal cancer; the combination is abbreviated as FOLFOX. Addition of irinotecan (see discussion that follows) is abbreviated as FOLFIRINOX and used in the treatment of patients with colorectal or pancreatic cancer. A most important interaction is the enhancement of irradiation by fluoropyrimidines, the basis for which is unclear. 5FU with simultaneous irradiation cures patients with anal cancer and enhances local tumor control in patients with head, neck, cervical, rectal, gastroesophageal, and pancreatic cancer.

**ADME**

5-Fluorouracil is administered parenterally because absorption after oral ingestion of the drug is unpredictable and incomplete. 5FU is inactivated
by reduction of the pyrimidine ring in a reaction carried out by DPD, which is found in liver, intestinal mucosa, tumor cells, and other tissues. Inherited deficiency of this enzyme leads to greatly increased sensitivity to the drug (Milano et al., 1999). DPD deficiency can be detected by either enzymatic or molecular assays using peripheral white blood cells or by determining the plasma ratio of 5FU to its metabolite, 5-fluoro-5,6-dihydroouracil.

Plasma clearance is rapid ($t_{1/2}$ about 10–20 min). Only 5%–10% of a single intravenous dose of 5FU is excreted intact in the urine. The dose does not have to be modified in patients with hepatic dysfunction, presumably because of sufficient degradation of the drug at extrahepatic sites. 5FU enters the CSF in minimal amounts.

### Therapeutic Uses

#### 5-Fluorouracil

5-Fluorouracil produces partial responses in 10%–20% of patients with metastatic colon carcinomas, upper GI tract carcinomas, and breast carcinomas but rarely is used as a single agent. 5FU in combination with leucovorin and oxaliplatin or irinotecan (FOLFOX and FOLFIRINOX) in adjuvant therapy is associated with a survival advantage for patients with colorectal cancers. For average-risk patients in good nutritional status with adequate hematopoietic function, the dosage regimen employs leucovorin once each week for 6 of 8 weeks. Other regimens use daily 5FU doses for 5 days at recommended times. When used with leucovorin, doses of daily 5FU for 5 days must be reduced because of mucositis and diarrhea. 5FU increasingly is used as a biweekly infusion, a schedule that has less overall toxicity as well as superior response rates and progression-free survival for patients with metastatic colon cancer.

Flouxuridine. Fluorodeoxyuridine is converted directly toFdUMP by thymidine kinase. The drug is administered primarily by continuous infusion into the hepatic artery for treatment of patients with metastatic carcinoma of the colon or following resection of hepatic metastases; the response rate of intrahepatic infusion (40%–50%) is twice that of intravenous administration. Intravenous infusion for 14–21 days causes minimal systemic toxicity; however, there is a significant risk of biliary sclerosis if this route is used for multiple cycles of therapy. Treatment should be discontinued at the earliest manifestation of toxicity (usually stomatitis or diarrhea) because the maximal effects of bone marrow suppression and gut toxicity will not be evident until days 7–14.

Capcitabine. Capecitabine, an orally administered prodrug of 5FU, is approved for the treatment of patients with (1) metastatic breast cancer who have not responded to a regimen of paclitaxel and an anthracycline; (2) metastatic breast cancer when used in combination with docetaxel in patients who have had a prior anthracycline-containing regimen; and (3) metastatic colorectal cancer. The recommended dosage is given in two divided doses with food, for 2 weeks, followed by a rest period of 1 week. Capecitabine is well absorbed orally. It is rapidly deesterified and deaminated, yielding high plasma concentrations of an inactive prodrug 5'-dFUDU, which disappears with a $t_{1/2}$ of about 1 h. The conversion of 5'-dFUDU to 5FU by thymidine phosphorylase occurs in liver tissues, peripheral tissues, and tumors. 5FU levels are less than 10% of those of 5'-dFUDU, reaching a maximum of 0.3 mg/L or 1 µM at 2 h. Liver dysfunction delays the conversion of the parent compound to 5'-dFUDU and 5FU, but there is no consistent effect on toxicity.

**Combination Therapy.** Higher response rates are seen when 5FU or capecitabine is used in combination with other agents (e.g., with cisplatin in head and neck cancer, with oxaliplatin or irinotecan in colon cancer). The combination of 5FU and oxaliplatin or irinotecan has become the standard first-line treatment of patients with metastatic colorectal cancer (FOLFOX and FOLFIRINOX). The use of 5FU in combination regimens has improved survival in the adjuvant treatment of breast cancer and, with oxaliplatin and leucovorin, of colorectal cancer. 5FU also is a potent radiation sensitizer. Beneficial effects have been reported when combined with irradiation as primary treatment of patients with locally advanced cancers of the esophagus, stomach, pancreas, cervix, anus, and head and neck. 5FU is effective in the topical treatment of premalignant keratoses of the skin and multiple superficial basal cell carcinomas.

### Adverse Effects

The clinical manifestations of toxicity caused by 5FU and fluorouridine are similar. The earliest untoward symptoms during a course of therapy are anorexia and nausea, followed by stomatitis and diarrhea, reliable warning signs that a sufficient dose has been administered. Mucosal ulcerations occur throughout the GI tract and may lead to fulminant diarrhea, shock, and death, particularly in patients who are DPD deficient. The major toxic effects of bolus-dose regimens result from the myelosuppressive action of 5FU. The nadir of leukopenia usually occurs 9–14 days after the first injection of drug. Thrombocytopenia and anemia also may occur, as may loss of hair (occasionally progressing to total alopecia), nail changes, dermatitis, and increased pigmentation and atrophy of the skin. Hand-foot syndrome, a particularly prominent adverse effect of capecitabine, consists of erythema, desquamation, pain, and sensitivity to touch of the palms and soles. Acute chest pain with evidence of ischemia in the electrocardiogram may result from coronary artery vasospasms during or shortly after 5FU infusion. In general, myelosuppression, mucositis, and diarrhea occur less often with infusional than with bolus regimens, while hand-foot syndrome occurs more often with infusional than with bolus regimens. The significant risk of toxicity with fluoropyrimidines requires close supervision by physicians familiar with the drug's effects and possible hazards.

Capcitabine causes a similar spectrum of toxicities as 5FU (diarrhea, myelosuppression), but the hand-foot syndrome occurs more frequently and may require dose reduction or cessation of therapy.

### Trifluridine

Trifluridine is a trifluoro nucleoside analogue of FUdR (see Figure 66–8). It is used in eye drops for the treatment of HSV and in a fixed combination with tipiracil, a thymidine phosphorylase inhibitor, for the treatment of patients with metastatic colorectal cancers who have previously received other standard combination treatments that included FOLFIRINOX. **Trifluridine and tipiracil** are formulated together in a single tablet with tipiracil added to prevent rapid breakdown of trifluridine. The trifluridine mechanism of action mimics that of 5FU (Davidson et al., 2016).

### Cytidine Analogues

**Cytarabine (Cytosine Arabinoside; Ara-C)**

Cytarabine is the most important antimetabolite used in the therapy of AML; it is the single most effective agent for induction of remission in this disease.

**Mechanisms of Action**

Cytarabine is an analogue of 2'-deoxycytidine; the 2'-hydroxyl of the sugar (see Figures 66–7 and 66–8) hinders rotation of the pyrimidine base around the nucleoside bond and interferes with base pairing. The drug enters cells via ENt1 (or SLC29A1). It is then converted to its active form, the 5'-monophosphate ribonucleotide, by dCK, an enzyme that shows polymorphic expression amongst patients (see discussion that follows). Ara-CMP then reacts with deoxy-nucleotidase kinases to form diphosphate and triphosphates (Ara-CDP and Ara-CTP). Ara-CTP competes with dCTP for incorporation into DNA by DNA polymerases. The incorporated Ara-CMP residue is a potent inhibitor of DNA polymerase, in both replication and repair synthesis, and blocks the further elongation of the nascent DNA molecule. If DNA breaks are not repaired, apoptosis ensues. Ara-C cytotoxicity correlates with the total Ara-C incorporated into DNA; incorporation of about 5 molecules of Ara-C per 10^6 bases of DNA decreases cellular clonogenicity by about 50% (Kufe et al., 1984).

In infants and adults with ALL and t(4;11) MLL translocation, high-dose Ara-C is particularly effective; in these patients, the nucleoside transporter ENT1 is highly expressed, and its expression correlates with sensitivity to Ara-C (Pui et al., 2004). At extracellular drug concentrations greater than 10 µg/mL (levels achievable with high-dose Ara-C), the nucleoside transporter no longer limits drug accumulation, and intracellular metabolism to a triphosphate becomes rate limiting. Patients with particular...
subtypes of AML derive benefit from high-dose Ara-C treatment; these types include t(8;21), inv(16), t(9;16), and del(16). Approximately 20% of patients with AML have leukemic cells with a KRAS mutation, and these patients seem to derive greater benefit from high-dose Ara-C regimens than do patients with wild-type KRAS.

**Mechanisms of Resistance**

Response to Ara-C is strongly influenced by the relative activities of anabolic and catabolic enzymes that determine the proportion of drug converted to Ara-CTP. The rate-limiting activating enzyme dCK produces Ara-CMP. It is opposed by the degradative enzyme, cytidine deaminase, which converts Ara-C to a nontoxic metabolite, Ara-U. Cytidine deaminase activity is high in many normal tissues, including intestinal mucosa, liver, and neutrophils, but lower in AML cells and other human tumors. A second degradative enzyme, dCMP deaminase, converts Ara-CMP to the inactive metabolite Ara-UMP. Increased synthesis and retention of Ara-CTP in leukemic cells lead to a longer duration of complete remission in patients with AML. The capacity of cells to transport Ara-C also may affect clinical response. Clinical studies have implicated a loss of dCK as the primary mechanism of resistance to Ara-C in AML.

**ADME**

Due to the presence of high concentrations of cytidine deaminase in the GI mucosa and liver, only about 20% of the drug reaches the circulation after oral Ara-C administration; thus, the drug must be given intravenously. Peak concentrations of 2–50 μM are measurable in plasma after intravenous injection of 30–300 mg/m² but fall rapidly (t₁/₂ = 10 min). Less than 10% of the injected dose is excreted unchanged in the urine within 12–24 h; most appears as the inactive deaminated product, Ara-U. Higher concentrations of Ara-C are found in CSF after continuous infusion than after rapid intravenous injection but are 10% or less of concentrations in plasma. After intrathecal administration of the drug at a dose of 50 mg/m², deamination proceeds slowly, with a t₁/₂ of 3–4 h, and peak concentrations of 1–2 μM are achieved. CSF concentrations remain above the threshold for cytotoxicity (0.4 μM) for 24 h or longer. A depot liposomal formulation of Ara-C provides sustained release into the CSF. After a standard dose, liposomal Ara-C remains above cytotoxic levels for an average of 12 days, thus avoiding the need for frequent lumbar punctures.

**Therapeutic Uses**

Continuous infusion of DNA synthesis for a duration equivalent to at least one cell cycle or 24 h is necessary to expose most tumor cells during the S phase of the cell cycle. The optimal interval between bolus doses of Ara-C is about 8–12 h, a schedule that maintains intracellular concentrations of Ara-CTP at inhibitory levels during a multiday cycle of treatment. In general, children tolerate higher doses than adults. The intrathecal administration of liposomal cytarabine every 2 weeks seems equally effective as the regimen every 4 days with the standard drug. Ara-C is indicated for induction and maintenance of remission in AML and is useful in the treatment of patients with other leukemias, such as ALL, CML in the blast phase, APL, and high-grade lymphomas. Because drug concentration in plasma rapidly falls below the level needed to saturate transport and intracellular activation, clinicians have employed high-dose regimens every 12 h for 3–4 days to achieve 20–50 times higher serum levels, with improved results in remission induction and consolidation for AML. Injection of the liposomal formulation is indicated for the intrathecal treatment of lymphomatous meningitis.

**Adverse Effects**

Cytarabine is myelosuppressive and can produce acute, severe leukopenia, thrombocytopenia, and anemia with striking megaloblastic changes. Other toxic manifestations include GI disturbances, stomatitis, conjunctivitis, reversible hepatic enzyme elevations, noncardiogenic pulmonary edema, and dermatitis. The onset of dyspnea, fever, and pulmonary infiltrates on chest computed tomographic scans may follow 1–2 weeks after high-dose Ara-C and may be fatal in 10%–20% of patients, especially in patients being treated for relapsed leukemia. No specific therapy, other than Ara-C discontinuation, is indicated. Intrathecal Ara-C, either the free drug or the liposomal preparation, may cause arachnoiditis, seizures, delirium, myelopathy, or coma, especially if given concomitantly with systemic high-dose MTX or systemic Ara-C. Cerebellar toxicity, manifesting as ataxia and slurred speech, and cerebral toxicity (seizures, dementia, and coma) may follow intrathecal administration or high-dose systemic administration, especially in patients older than 40 years or patients with poor renal function.

**Azacitidine (5-Azacytidine); Decitabine**

5-Azacytidine (Figure 66–7) and decitabine (2′-deoxy-5-azacytidine; Figure 66–8) have antileukemic activity and induce differentiation by inhibiting cytosine methyltransferase activity. Both drugs are approved for treatment of myelodysplasia, for which they induce normalization of bone marrow in 15%–20% of patients and reduce the transfusion requirement in one-third of patients. 5-Azacytidine improves survival.

**Mechanism of Action**

Theaza-nucleosides enter cells by ENT1 (SLC29A1). The drugs incorporate into DNA, where they become covalently bound to the DNA methyltransferase, depleting intracellular nucleotides that become incorporated into DNA, the effects of theaza-nucleosides persist for many hours.

**ADME**

After subcutaneous administration, 5-azacytidine undergoes rapid deamination by cytidine deaminase (plasma t₁/₂ = 20–40 min). Due to the formation of intracellular nucleotides that become incorporated into DNA, the major toxicities of theaza-nucleosides persist for many hours.

**Therapeutic Use**

The usual treatment regimen for 5-azacytidine in patients with MDS is daily for 7 days every 28 days, while decitabine is given intravenously every day for 5 days every 4 weeks. Best responses may become apparent only after two to five courses of treatment.

**Adverse Effects**

The major toxicities of theaza-nucleosides include myelosuppression and mild GI symptoms. 5-Azacytidine produces severe nausea and vomiting when given intravenously in large doses (150–200 mg/m²/d for 5 days).

**Gemcitabine**

Gemcitabine, a difluoro analogue of deoxycytidine (dFdC; see Figure 66–8), is used for patients with metastatic pancreatic; non-squamous, non–small cell lung; ovarian; and bladder cancer.

**Mechanism of Action**

Gemcitabine enters cells via three distinct nucleoside transporters: ENT1 (SLC29A1; the major route); CNT1 (SLC28A1); and a nucleobase transporter found in malignant mesothelioma cells. Intracellularly, dCK phosphorylates gemcitabine to the monophosphate (dFdCMP), which is converted to di- and triphosphates (dFdCDP and dFdCTP, respectively). Although gemcitabine’s anabolism and effects on DNA in general mimic those of cytarabine, there are distinct differences in kinetics of inhibition, additional enzymatic sites of action, different effects of incorporation into DNA, and a distinct spectrum of clinical activity. Unlike that of cytarabine, the cytotoxicity of gemcitabine is not confined to the S phase of the cell cycle. The cytotoxic activity may reflect several actions on DNA synthesis. dFdCTP competes with dCTP as a weak inhibitor of DNA polymerase. dFdCDP and dFdCTP, respectively. Gemcitabine’s mechanism of action involves inhibition of DNA synthesis and subsequent induction of apoptosis. Gemcitabine is inactivated by cytidine deaminase, which is found both in tumor cells and throughout the body.

**ADME**

Gemcitabine is administered as an intravenous infusion. The pharmacokinetics of the parent compound are largely determined by deamination in liver, plasma, and other organs, and the predominant urinary elimination product is dFdU. In patients with significant renal dysfunction, dFdU and
its triphosphate accumulate to high and potentially toxic levels. Gemicitabine has a short plasma \( t_{1/2} \) (~15 min); women and elderly patients clear the drug more slowly.

**Therapeutic Uses**

The standard dosing schedule for gemcitabine is an intravenous infusion on days 1, 8, and 15 of each 21- to 28-day cycle, depending on the indication. Conversion of gemcitabine to dFdCMP by dCK is saturated at infusion rates of about 10 mg/m²/min. To increase dFdCTP formation, the duration of infusion at this maximum concentration has been extended to 100–150 min at a fixed rate of 10 mg/min. The 150-min infusion produces a higher level of dFdCTP within peripheral blood mononuclear cells and increases the degree of myelosuppression. The inhibition of DNA repair by gemcitabine may increase cytotoxicity of other agents, particularly platinum compounds, and with radiation therapy.

**Adverse Effects**

The principal toxicity is myelosuppression. Longer duration infusions lead to greater myelosuppression and hepatic toxicity. Nonhematological toxicities include a flu-like syndrome, asthenia, and rarely a posterior leukoencephalopathy syndrome. Mild, reversible elevation in liver transaminases may occur in 40% or more of patients. Interstitial pneumonitis, at times progressing to ARDS, may occur within the first two cycles of treatment and usually responds to corticosteroids. Rarely, patients treated for many months may develop a slowly progressive hemolytic uremic syndrome, necessitating drug discontinuation. Gemicitabine is a very potent radiosensitizer and should not be used with radiotherapy.

**Purine Analogue**

The pioneering studies of Hitchings and Elion identified analogues of naturally occurring purine bases with antileukemic and immunosuppressant properties. Figure 66–9 shows structural formulas of several purine analogues, with adenosine for comparison. Other purine analogues that have valuable roles in leukemia and lymphoid malignancies include cladribine (standard therapy of hairy cell leukemia), fludarabine phosphate (standard treatment of CLL), nelarabine (pediatric ALL), and clofarabine (T-cell leukemia/lymphoma). The apparent selectivity of these agents may relate to their effective uptake, activation, and apoptotic effects in lymphoid tissue.

**6-Thiopurine Analogue**

6-Mercaptopurine and 6TG are approved agents for human leukemias and functions as analogues of the natural purines hypoxanthine and guanine. The substitution of sulfur for oxygen on C6 of the purine ring creates compounds that are readily transported into cells, including activated malignant cells. Nucleotides formed from 6MP and 6TG inhibit de novo purine synthesis and also become incorporated into nucleic acids (Figure 51–5).

**Mechanism of Action**

Hypoxanthine guanine phosphoribosyl transferase converts 6TG and 6MP to the ribonucleotides 6-thioGMP and 6-thioIMP (T-IMP), respectively. Because T-IMP is a poor substrate for guanylyl kinase (the enzyme that converts GMP to GDP), T-IMP accumulates intracellularly. T-IMP inhibits the new formation of ribosyl-5-phosphate, as well as conversion of IMP to adenine and guanine nucleotides. The most important point of attack seems to be the reaction of glutamine and PRPP to form ribosyl-5-phosphate, the first committed step in the de novo pathway. 6TG nucleotide is incorporated into DNA, where it induces strand breaks and base mispairing.

**Mechanisms of Resistance**

The most common mechanism of 6MP resistance observed in vitro is deficiency or complete lack of the activating enzyme HPRT or increased alkaline phosphatase activity. Other mechanisms for resistance include:

- decreased drug uptake or increased efflux due to active transporters;
- alteration in allosteric inhibition of ribosylamine 5-phosphate synthase;
- impaired recognition of DNA breaks and mismatches due to loss of a component (MSH6) of MMR system (Karran and Attard, 2008).

**Adenosine and Toxicity**

Absorption of oral mercaptopurine is incomplete (10%–50%); the drug is subject to first-pass metabolism by xanthine oxidase in the liver. Food or oral antibiotics decrease absorption. Oral bioavailability is increased when mercaptopurine is combined with high-dose MTX. After an intravenous dose, the \( t_{1/2} \) of the drug is about 50 min in adults due to rapid metabolic degradation by xanthine oxidase and by TPMT. Restricted brain distribution of mercaptopurine results from an efficient efflux transport system in the blood-brain barrier. In addition to the HPRT-catalyzed anabolism of mercaptopurine, there are two other pathways for its metabolism. The first involves methylation of the sulfhydryl group and subsequent oxidation of the methylated derivatives. Activity of the enzyme TPMT reflects the inheritance of polymorphic alleles; up to 15% of the Caucasian population has decreased enzyme activity. Low levels of erythrocyte TPMT activity are associated with increased drug toxicity in individual patients and a lower risk of relapse. In patients with autoimmune disease treated with mercaptopurine, those with polymorphic alleles may experience bone marrow aplasia and life-threatening toxicity. Testing for these polymorphisms prior to treatment is recommended in this patient population. A relatively large percentage of the administered sulfur appears in the urine as inorganic sulfate. The second major pathway for 6MP metabolism involves its oxidation by xanthine oxidase to 6-thiourate, an inactive metabolite. Oral doses of 6MP should be reduced by 75% in patients receiving the xanthine oxidase inhibitor allopurinol; no dose adjustment is required for intravenous dosing.

**Therapeutic Uses**

In the maintenance therapy of ALL, an initial daily oral dose of 6MP is adjusted according to white blood cell and platelet counts. The combination of MTX and 6MP appears to be synergistic. By inhibiting the earliest steps in purine synthesis, MTX elevates the intracellular concentration of PRPP, a cofactor required for 6MP activation.

![Figure 66–9 Adenosine and various purine analogues.](image-url)
Adverse Effects
The principal toxicity of 6MP is myelosuppression. Thrombocytopenia, granulocytopenia, or anemia may not become apparent for several weeks. Dose reduction usually results in prompt recovery, although myelosuppression may be severe and prolonged in patients with a polymorphism affecting TPMT. Anorexia, nausea, or vomiting is seen in about 25% of adults, but stomatitis and diarrhea are rare; manifestations of GI effects are less frequent in children than in adults. Jaundice and hepatic enzyme elevations occur in up to one-third of adult patients treated with 6MP and usually resolve on discontinuation of therapy. 6MP and its derivative azathioprine predispose to opportunistic infection (e.g., reactivation of hepatitis B, fungal infection, and Pneumocystis pneumonia) and an increased incidence of squamous cell malignancies of the skin. 6MP is teratogenic during the first trimester of pregnancy, and AML has been reported after prolonged 6MP therapy for Crohn disease.

Fludarabine Phosphate
Fludarabine phosphate is a fluorinated, deamination-resistant, phosphorylated analogue of the antiviral agent vidarabine (9-β-D-arabinofuranosyl-adenine). It is active in CLL and low-grade lymphomas and is also effective as a potent immunosuppressant.

Mechanisms of Action and Resistance
The drug is dephosphorylated extracellularly to the nucleoside fludarabine, which enters the cell and is phosphorylated by dCK to the active triphosphate. This antimitabolite inhibits DNA polymerase, DNA primase, DNA ligase, and RNR and becomes incorporated into DNA and RNA. The nucleotide is an effective chain terminator when incorporated into DNA (Kamiya et al., 1996). Incorporation of fludarabine into RNA inhibits RNA function, RNA processing, and mRNA translation.

In experimental tumors, resistance to fludarabine is associated with decreased activity of dCK (the enzyme that phosphorylates the drug), increased drug efflux, and increased RNR activity. Its mechanism of immunosuppression and paradoxical stimulation of autoimmunity stems from the particular susceptibility of lymphoid cells to purine analogues and the specific effects on the CD4+ subset of T cells, as well as its inhibition of regulatory T-cell responses.

ADME
Fludarabine phosphate is administered both intravenously and orally and is rapidly converted to fludarabine in the plasma. The median time to reach maximal concentrations of drug in plasma after oral administration is 1.5 h, and oral bioavailability averages 55%–60%. The t1/2 of fludarabine in plasma is about 10 h. The compound is eliminated primarily by renal excretion.

Therapeutic Uses
Fludarabine phosphate is approved for intravenous and oral use and is equally active by both routes. The recommended dose interval is daily for 5 days and may be repeated every 4 weeks. Gradual improvement in CLL usually occurs within 2 to 3 cycles. Dosage should be reduced in patients with renal impairment in proportion to the reduction in ClCr. Fludarabine phosphate is highly active alone or with rituximab and cyclophosphamide for the treatment of patients with CLL; overall response rates in previously untreated patients approximate 80%, and the duration of response averages 22 months. The synergy of fludarabine with alkylators may stem from the observation that it blocks the repair of double-strand DNA breaks and interstrand cross-links induced by alkylating agents. It also is effective in follicular B-cell lymphomas refractory to standard therapy. It is increasingly used as a potent immunosuppressive agent in nonmyeloblastic allogeneic bone marrow transplantation.

Adverse Effects
Oral and intravenous therapy cause myelosuppression in about 50% of patients, nausea and vomiting in a minor fraction, and, uncommonly, chills and fever, malaise, anorexia, peripheral neuropathy, and weakness. Lymphopenia and thrombocytopenia and cumulative side effects are expected. Depletion of CD4+ T cells with therapy predisposes to opportunistic infections. Tumor lysis syndrome, a rare complication, occurs primarily in previously untreated patients with CLL. Altered mental status, seizures, optic neuritis, and coma have been observed at higher doses and in older patients. Autoimmune events may occur after fludarabine treatment. Patients with CLL may develop an acute hemorrhagic anemia or pure red cell aplasia during or following fludarabine treatment. Prolonged cytophenias, probably mediated by autoimmunity, also complicate fludarabine treatment. Myelodysplasia and acute leukemias may arise as late complications. Pneumonitis is an occasional side effect and responds to corticosteroids. In patients with compromised renal function, the initial doses should be reduced in proportion to the reduction in ClCr.

Cladribine
Cladribine is an ADA-resistant purine analogue that has potent and curative activity in hairy cell leukemia, CLL, and low-grade lymphomas.

Mechanisms of Action and Resistance
Cladribine enters cells via active nucleoside transport. After phosphorylation by dCK and conversion to cladribine triphosphate, it is incorporated into DNA. It produces DNA strand breaks and depletion of NAD and ATP leading to apoptosis. It is a potent inhibitor of RNR. The drug does not require cell division to be cytotoxic. Resistance is associated with loss of the activating enzyme dCK; increased expression of RNR; or increased active efflux by ABCG2 or other members of the ABC family of transporters.

ADME
Cladribine is absorbed orally (55%) but is routinely administered intravenously. It is excreted by the kidneys, with a terminal t1/2 in plasma of 6.7 h. Cladribine crosses the blood-brain barrier and reaches CSF concentrations of about 25% of those seen in plasma. Doses should be adjusted for renal dysfunction.

Therapeutic Uses
Cladribine is administered daily for 7 days by continuous intravenous infusion. It is the drug of choice in hairy cell leukemia. Eighty percent of patients achieve a complete response after a single course of therapy. The drug also is active in CLL; low-grade lymphomas; Langerhans cell histiocytosis; CTCLs, including mycosis fungoides and the Sézary syndrome; and Waldenström macroglobulinemia.

Adverse Effects
The major dose-limiting toxicity of cladribine is myelosuppression. Cumulative thrombocytopenia may occur with repeated courses. Opportunistic infections are common and correlate with decreased CD4+ cell counts. Other toxic effects include nausea, infections, high fever, headache, fatigue, skin rashes, and tumor lysis syndrome.

Clofarabine (2-Chloro-2′-fluoroarabinosyladenine)
The analogue clofarabine (2-chloro-2′-fluoroarabinosyladenine) incorporates the 2-chloro, glycosylase-resistant substituent of cladribine and a 2′-fluoro-arabinosyl substitution, which adds stability and enhances uptake and phosphorylation. The resulting compound is approved for the treatment of pediatric ALL after failure of two prior therapies. Clofarabine produces complete remissions in 20%–30% of these patients.
It has activity in pediatric and adult AML and in myelodysplasia. The uptake and metabolic activation of clofarabine in tumor cells follow the same path as cladrabine and the other purine nucleosides, although clofarabine is more readily phosphorylated by dCK. Clofarabine triphosphate has a long intracellular $t_{1/2}$ (24 h). It incorporates into DNA, where it terminates DNA synthesis and leads to apoptosis; clofarabine also inhibits RNR.

**Therapeutic Uses and Adverse Effects**

In children, clofarabine is administered as a 2-h infusion daily for 5 days. The primary elimination $t_{1/2}$ in plasma is 6.5 h. Most of the drug is excreted unchanged in the urine. Doses should be adjusted according to reductions in ClCr. The primary toxicities are myelosuppression; a clinical syndrome of hypotension, tachyphemia, pulmonary edema, organ dysfunction, and fever, all suggestive of capillary leak syndrome and cytokine release that necessitate immediate discontinuation of the drug; elevated hepatic enzymes and increased bilirubin; nausea, vomiting, and diarrhea; and hyponatremia and hypophosphatemia.

**Nelarabine (6-Methoxy-arabinosyl-guanine)**

Nelarabine (6-methoxy-arabinosyl-guanine) is the only guanine nucleoside in clinical use. It has selective activity against acute T-cell leukemia (20% complete responses) and the closely related T-cell lymphoblastic lymphoma and is approved for use in patients with relapsed/refractory disease. Its basic mechanism of action closely resembles that of the other purine nucleosides, in that it is incorporated into DNA and terminates DNA synthesis.

**ADME**

Following infusion, the parent methoxy compound is rapidly activated in blood and tissues by ADA–mediated cleavage of the methyl group, yielding the phosphorylase resistant Ara-G, which has a plasma $t_{1/2}$ of 3 h. The active metabolite is transported into tumor cells, where it is activated by dCK to Ara-GTP, which incorporates into DNA and terminates DNA synthesis. The drug and its metabolite Ara-G are primarily eliminated by metabolism to guanine, and a smaller fraction is eliminated by renal excretion of Ara-G. The drug should be used with close clinical monitoring in patients with severe renal impairment (ClCr < 50 mg/mL). Adults are given a 2-h infusion on days 1, 3, and 5 of a 21-day cycle, and children are given a lower dose for 5 days, repeated every 21 days.

**Adverse Effects**

The adverse effects include myelosuppression and liver function test abnormalities, as well as infrequent serious neurological sequelae, such as seizures, delirium, somnolence, peripheral neuropathy, or Guillain-Barré syndrome. Neurological adverse effects may not be reversible.

**Pentostatin (2′-Deoxycoformycin)**

Pentostatin (2′-deoxycoformycin; see Figure 66–9), a transition-state analogue of the intermediate in the ADA reaction, potently inhibits ADA. Its effects mimic the phenotype of genetic ADA deficiency (severe immunodeficiency affecting T-cell and B-cell functions).

**Mechanism of Action**

Inhibition of ADA by pentostatin leads to accumulation of intracellular adenosine and deoxyadenosine nucleotides, which can block DNA synthesis by inhibiting RNR. Deoxyadenosine also inactivates S-adenosyl homocysteine hydrolase. The resulting accumulation of S-adenosyl homocysteine is particularly toxic to lymphocytes. Pentostatin also can inhibit RNA synthesis, and its triphosphate derivative is incorporated into DNA, resulting in strand breakage. Although the precise mechanism of cytotoxicity is not known, it is probable that the imbalance in purine nucleotide pools accounts for its antineoplastic effect in hairy cell leukemia and T-cell lymphomas.

**ADME**

Pentostatin is administered intravenously every other week and has a mean terminal $t_{1/2}$ of 5.7 h. After hydration with 500–1000 mL of 5% dextrose in half-normal (0.45%) saline, the drug is administered by rapid intravenous injection or by infusion over a period of 30 min or less, followed by an additional 500 mL of fluids. The drug is eliminated almost entirely by renal excretion. Proportional reduction of dosage is recommended in patients with renal impairment as measured by reduced ClCr.

**Therapeutic Use**

Pentostatin is effective in producing complete remissions (58%) and partial responses (28%) in patients with hairy cell leukemia. It largely has been superseded by cladribine (see previous discussion). Toxic manifestations include myelosuppression, GI symptoms, skin rashes, and abnormal liver function studies. Depletion of normal T cells occurs, and neutropenic fever and opportunistic infections may result. Immunosuppression may persist for several years after discontinuation. At high doses, major renal and neurological complications are encountered. Pentostatin in combination with fludarabine phosphate may result in severe or even fatal pulmonary toxicity.

### III. Natural Products

**Microtubule-Damaging Agents**

**Vinca Alkaloids**

Purified alkaloids from the periwinkle plant, including vinblastine and vincristine, were amongst the earliest clinical agents for the treatment of patients with leukemias, lymphomas, and testicular cancer. A closely related derivative, vinorelbine, has activity against lung and breast cancer.

![Basic structure of vinca alkaloids](image-url)

**Mechanism of Action**

The vinca alkaloids are cell-cycle–specific agents and, in common with other drugs, such as colchicine, podophyllotoxin, the taxanes, and the epothilones, block cells in mitosis. The biological activities of the vincas can be explained by their ability to bind specifically to β-tubulin and to block its polymerization with α-tubulin into microtubules (Akhmanova and Steinmetz, 2015). The mitotic spindle cannot form, duplicated chromosomes cannot align along the division plate, and cell division arrests in metaphase. Cells blocked in mitosis undergo changes characteristic of apoptosis. Microtubules are found in high concentration in the brain and contribute to other cellular functions, such as movement, phagocytosis, and axonal transport. Adverse effects of the vinca alkaloids, such as their neurotoxicity, may relate to disruption of these functions.

**Resistance**

Despite their structural similarity, the individual vinca alkaloids have unique patterns of clinical efficacy (see discussion that follows). However, in most experimental systems, they share cross-resistance. Their antitumor effects are blocked by multidrug resistance mediated by Pgp, which confers resistance to a broad range of agents (vinca alkaloids, epipodophyllotoxins, anthracyclines, and taxanes). Pgp, also known as MDR1, ABCB1, and CD243, is an ATP-dependent efflux pump with broad substrate specificity that provides a cellular defense mechanism against potentially harmful substances. Chromosomal abnormalities consistent with gene amplification and markedly increased levels of Pgp have been
observed in resistant cells in culture. Other membrane transporters, such as the MRP and the closely related BCRP, may contribute to resistance. Other forms of resistance to vinca alkaloids stem from mutations in β-tubulin or in the relative expression of isoforms of β-tubulin that prevent the inhibitors from effectively binding to their target.

**Adverse Effects**
The limited myelosuppressive activity of vincristine makes it a valuable component of several combination therapy regimens for leukemia and lymphoma, while the lack of severe neurotoxicity of vinblastine is a decided advantage in lymphomas and in combination with cisplatin against testicular cancer. Vinorelbine, which causes mild neurotoxicity and myelosuppression, has an intermediate toxicity profile.

**ADME**
Hepatic CYPs extensively metabolize all three drugs, and the metabolites are excreted in the bile. Only a small fraction of a dose (<15%) is found unchanged in the urine. In patients with hepatic dysfunction (bilirubin > 3 mg/dL), a 50%–75% reduction in dose of any of the vinca alkaloids is advisable. The elimination t1/2 is 20 h for vincristine, 23 h for vinblastine, and 24 h for vinorelbine.

**Vinblastine**

**Therapeutic Uses.** Vinblastine sulfate is given intravenously; special precautions must be taken against subcutaneous extravasation, which may cause painful irritation and ulceration. The drug should not be injected into an extremity with impaired circulation. After a single dose, myelosuppression reaches its maximum in 7–10 days. If a moderate level of leukopenia (~3000 cells/mm3) is not attained, the weekly dose may be increased gradually. For testicular cancer, vinblastine is administered every 3 weeks. Doses should be reduced by 50% for patients with plasma bilirubin > 1.5 mg/dL. Vinblastine is used with bleomycin and cisplatin in the curative therapy of patients with metastatic testicular cancer, although it has been mainly supplanted by etoposide (see further discussion) or ifosfamide (see previous material). It is a component of the standard curative ABVD regimen for Hodgkin lymphoma. Vinblastine also is active against Kaposi sarcoma, neuroblastoma, Langerhans cell histiocytosis, bladder cancer, carcinoma of the breast, and choriocarcinoma.

**Adverse Effects.** Maximal leukopenia occurs within 7–10 days, after which recovery ensues within 7 days. Other toxic effects of vinblastine include mild neurological manifestations. GI disturbances, including nausea, vomiting, anorexia, and diarrhea, may be encountered. The syndrome of inappropriate secretion of antidiuretic hormone has been reported. Hair loss, stomatitis, and dermatitis occur infrequently. Extravasation during injection may lead to cellulitis and phlebitis.

**Vincristine**

**Therapeutic Uses.** Vincristine is a standard component of regimens for treating pediatric patients with leukemias, lymphomas, and solid tumors, such as Wilms tumor, neuroblastoma, and rhabdomyosarcoma. In large-cell non-Hodgkin lymphomas, vincristine remains an important agent, particularly when used in the CHOP regimen. Vincristine with glucocorticoids is the treatment of choice to induce remissions in patients with elevated plasma bilirubin.

**Adverse Effects.** The clinical toxicity of vincristine is mostly neurological. Severe neurological manifestations may be reversed by suspending therapy or reducing the dosage at the first sign of motor dysfunction. Severe constipation, sometimes resulting in colicky abdominal pain and obstruction, may be prevented by laxatives and hydrophilic (bulk-forming) agents and usually is a problem only with doses greater than 2 mg/m2. Reversible alopecia occurs in about 20% of patients. Modest leukopenia may occur. Thrombocytopenia, anemia, and the syndrome of inappropriate secretion of antidiuretic hormone are less common. Inadvertent injection of vincristine into the CSF causes a devastating and often-fatal irreversible coma and seizures.

**Vinorelbine**
Vinorelbine has activity against non–small cell lung cancer and breast cancer. Vinorelbine is administered in normal saline as an intravenous infusion over 6–10 min. When used alone, it is given at doses of 30 mg/m2 either weekly or for 2 of every 3 weeks. When used with cisplatin for the treatment of non–small cell lung cancer, it is given at doses of 25 mg/m2 either weekly or for 3 of every 4 weeks. A lower dose (20–25 mg/m2) may be required for patients who have received prior chemotherapy and for hematological toxicity. The primary adverse effect of vinorelbine is granulocytopenia, with only modest thrombocytopenia and less neurotoxicity than other vinca alkaloids. Vinorelbine may cause allergic reactions and mild, reversible changes in liver enzymes. Doses should be reduced in patients with elevated plasma bilirubin.

**Eribulin**
Eribulin is a synthetic analogue of halichondrin, a poly-ether macrolide, originally isolated from the Pacific marine sponge Halichondria okadae. The drug binds to the vinca alkaloid site on β-tubulin and inhibits microtubule assembly. Eribulin is a poorer substrate than other microtubule disruptors for the Pgp efflux pump and is effective in drug-resistant tumors that overexpress Pgp. Eribulin is approved for the treatment of patients with drug-resistant metastatic breast cancer and liposarcoma. Adverse effects overlap with those of the vinca alkaloids and include neutropenia, neuropathies, and GI toxicities.

**Taxanes**
Paclitaxel was first isolated from the bark of the Western yew tree. Paclitaxel and its semisynthetic congeners docetaxel and cabazitaxel, exhibit unique pharmacological properties as inhibitors of mitosis. These taxanes differ from the vinca alkaloids and colchicine derivatives in that they bind to a different site on β-tubulin and promote rather than inhibit microtubule formation (Figure 66–10), stabilizing tubulin-GDP (Akhmanova and Steinmetz, 2015). The taxanes have a central role in the therapy of patients with ovarian, breast, lung, GI, genitourinary, prostate, and head and neck cancers.
CHAPTER 66
CYTOTOXIC DRUGS

Mechanism of Action
Paclitaxel binds to the β-tubulin subunit on the inner surface of microtubules and antagonizes their disassembly (Figure 66–10), with the result that bundles of microtubules are aberrant structures derived from microtubules appear in the mitotic phase of the cell cycle. Arrest in mitosis follows. Cell death occurs by apoptosis and depends on both drug concentration and duration of drug exposure. Drugs that block cell-cycle progression prior to mitosis antagonize the toxic effects of taxanes.

Drug interactions have been noted. The sequence of cisplatin preceding paclitaxel decreases paclitaxel clearance and produces greater toxicity than the opposite schedule. Paclitaxel decreases doxorubicin clearance and enhances its cardiotoxicity; docetaxel has no apparent effect on anthracycline pharmacokinetics.

Resistance to taxanes can be a result of decreased cellular drug accumulation due to increased expression of membrane-bound efflux proteins, including MRP1 and Pgp. Cabazitaxel is a poor substrate for Pgp and may therefore be useful for treating multidrug-resistant tumors. Other mechanisms of resistance may include an increase in survivin, an anti-apoptotic factor; an increase in a-aurora kinase, which promotes completion of mitosis; an upregulation of the βIII-isofrom of tubulin that lacks taxane-binding capacity; or a direct alteration of the drug target by mutation.

ADME
Paclitaxel has limited water solubility and is administered in a vehicle of 50% ethanol and 50% polyethoxylated castor oil. Hepatic CYPs (primarily CYP2C8, secondarily CYP3A4) extensively metabolize the drug. The primary metabolite is 6-OH paclitaxel, which is inactive; multiple additional hydroxylation products are found in plasma; less than 10% of a dose is excreted in the urine intact. Dose reductions in patients with abnormal hepatic function have been suggested, and 50–75% of doses of taxanes should be used in the presence of hepatic metastases larger than 2 cm in size or in patients with abnormal serum bilirubin. Drugs that induce CYP2C8 or CYP3A4, such as phenytoin and phenobarbital, or those that inhibit these CYPs, such as antifungal imidazoles, significantly alter drug clearance and toxicity.

Paclitaxel clearance is nonlinear and decreases with increasing dose or dose rate; the plasma t1/2 is 10–14 h. The critical plasma concentration for myelosuppression depends on the duration of exposure but likely is 50–100 nM. Paclitaxel clearance is markedly delayed by cyclosporine A and other drugs that inhibit Pgp.

An albumin-bound nanoparticle solution for infusion (nab-paclitaxel) is soluble in aqueous solutions. This form of paclitaxel has increased cellular uptake via an albumin-specific mechanism. Nab-paclitaxel achieves a higher serum concentration than paclitaxel, but the increased clearance of nab-paclitaxel results in a similar systemic drug exposure. It is somewhat less neurotoxic than paclitaxel and is approved for metastatic non–small cell lung cancer. Like the other taxanes, nab-paclitaxel should not be given to patients with an absolute neutrophil count below 1500 cells/mm3.

Docetaxel, somewhat more soluble than paclitaxel, is administered intravenously in an emulsifier (polysorbate 80). Docetaxel pharmacokinetics are similar to those of paclitaxel, with an elimination t1/2 of about 12 h. Clearance is primarily through CYP3A4- and CYP3A5-mediated hydroxylation, leading to inactive metabolites.

Therapeutic Uses
The taxanes have become central components of regimens for treating patients with metastatic ovarian, breast, lung, GI, genitourinary, and head and neck cancers. These drugs are administered once weekly or once every 3 weeks. Cabazitaxel is a poor substrate for Pgp and is approved for hormone-refractory metastatic prostate cancer previously treated with a docetaxel-containing regimen.

Adverse Effects
Paclitaxel exerts its primary toxic effects on the bone marrow. Neutropenia usually occurs 8–11 days after a dose and reverses rapidly by days 15–21. Used with G-CSF, high doses over 24 h are well tolerated, and peripheral neuropathy becomes dose limiting. Many patients experience myalgias after receiving paclitaxel. In high-dose schedules, or with prolonged use, a stocking-glove sensory neuropathy can be disabling, particularly in patients with underlying diabetic neuropathy or concurrent cisplatin therapy. Mucositis is prominent in 72- or 96-h infusions and in the weekly schedule. Hypersensitivity reactions can occur in patients receiving paclitaxel infusions of short duration (1–6 h) but are largely averted by pretreatment with dexamethasone, diphenhydramine, and histamine H1 receptor antagonists. Premedication is not necessary with 96-h infusions. Many patients experience asymptomatic bradycardia; occasional episodes of silent ventricular tachycardia also occur and resolve spontaneously during 3- or 24-h infusions. Nab-paclitaxel produces increased rates of peripheral neuropathy compared to the original cremophor-delivered paclitaxel but rarely causes hypersensitivity reactions.

Docetaxel causes greater degrees of neutropenia than paclitaxel but less peripheral neuropathy and asthenia and less frequent hypersensitivity. Fluid retention is a progressive problem with multiple cycles of docetaxel therapy, leading to peripheral edema, pleural and peritoneal fluid, and pulmonary edema in extreme cases. Oral dexamethasone, begun 1 day prior to drug infusion and continuing for 3 days, greatly ameliorates fluid retention. In rare cases, docetaxel may cause progressive interstitial pneumonia and respiratory failure if the drug is not discontinued.

Estramustine
Estramustine combines estradiol and normustine (nitrogen mustard) through a carbamate link. Although the extent of the combination was to enhance the uptake of the alkylating agent into estradiol-sensitive prostate cancer cells, estramustine does not function in vivo as an alkylating agent; rather, it binds to β-tubulin and microtubule-associated proteins, causing microtubule disassembly and antimitotic actions.

Therapeutic Use
Estramustine is used solely for the treatment of patients with metastatic or locally advanced hormone-refractory prostate cancer.

ADME
Following oral administration, at least 75% of a dose of estramustine phosphate is absorbed from the GI tract and rapidly dephosphorylated. The drug undergoes extensive first-pass metabolism by hepatic CYPs to an active 17-keto derivative, estramustine, and to multiple inactive products; the active drug forms accumulate in the prostate. Some hydrolysis of the carbamate linkage occurs in the liver, releasing estradiol, estrone, and the normustine group. Estramustine and estromustine have plasma half-lives of 10 and 14 h, respectively, and are excreted as inactive metabolites, mainly in the feces.

Adverse Effects, Drug Interactions
In addition to myelosuppression, estramustine also possesses estrogenic side effects (gynecomastia, impotence, elevated risk of thrombosis, and fluid retention); hypercalcemia; acute attacks of porphyria; impaired glucose tolerance; and hypersensitivity reactions, including angioedema. Estramustine inhibits the clearance of taxanes.

Epothilones
The epothilones are polyketides discovered as cytotoxic metabolites from a strain of Sorangium cellulosum, a myxobacterium isolated from soil on the island of the Zambezi River in southern Africa (Gerth et al., 1996). One of these, ixabepilone, is approved for breast cancer treatment; others are under development (Lee and Swain, 2008).
Ixabepilone

Mechanism of Action; Resistance. Epothilones bind to a β-tubulin site distinct from that of taxanes and trigger microtubule nucleation at multiple sites away from the centriole. This dysfunctional microtubule stabilization triggers cell-cycle arrest at the G_{2}-M interface and apoptosis. In vitro studies suggested that ixabepilone is less susceptible to Pgp-mediated export and multidrug resistance than taxanes. Mechanisms implicated in epothilone resistance include mutation of the β-tubulin binding site and upregulation of isomers of β-tubulin.

ADME. Ixabepilone is administered intravenously. Because of its minimal aqueous solubility, it is delivered in the solubilizing agent cremophor (polyoxyethylated castor oil/ethanol), which has been implicated as the cause of infusion reactions; such reactions are infrequent when administration is preceded by premedication with H_{1} and H_{2} antagonists. The drug is cleared by hepatic CYPs and has a plasma t_{1/2} of 52 h.

Therapeutic Uses. In patients with metastatic breast cancer resistant to or pretreated with anthracyclines and resistant to taxanes, ixabepilone plus capecitabine provides an improved progression-free survival of 1.6 months compared to capecitabine alone. Ixabepilone also is indicated as monotherapy for metastatic breast cancer in patients who have previously progressed through treatment with anthracyclines, taxanes, and capecitabine. Ixabepilone (~40 mg/m^{2}) is administered as monotherapy or in combination with capecitabine over 3 h every 3 weeks. Patients should be premedicated with both an H_{1} and an H_{2} antagonist before receiving ixabepilone to minimize hypersensitivity reactions. In patients with mild-to-moderate hepatic dysfunction who receive ixabepilone monotherapy, lower starting doses are recommended due to delayed drug clearance.

Adverse Effects. Epothilones have toxicities similar to those of the taxanes: neutropenia, peripheral sensory neuropathy, fatigue, diarrhea, and asthenia.

Camptothecin Analogues

The camptothecins are potent, cytotoxic antineoplastic agents that target the nuclear enzyme topoisomerase I. The lead compound in this class, camptothecin, was isolated from the tree Camptotheca acuminata. Irinotecan and topotecan, currently the only camptothecin analogues approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer.

Chemistry

All camptothecins have a fused five-ring backbone that includes a labile lactone ring (Figure 66–11). The hydroxyl group and S conformation of C-10. The lead compound in this class, camptothecin, was isolated from the tree Camptotheca acuminata. Irinotecan and topotecan, currently the only camptothecin analogues approved for clinical use, have activity in colorectal, ovarian, and small cell lung cancer. Camptothecins are S phase-specific drugs because ongoing DNA synthesis is necessary for cytotoxicity. This has important clinical implications. S phase-specific cytotoxic agents generally require prolonged exposures of tumor cells to drug concentrations above a minimum threshold for optimal therapeutic efficacy. In fact, low-dose, protracted administration of camptothecin analogues have less toxicity, and equal or greater antitumor activity, than shorter, more intense courses.

Mechanisms of Resistance

Decreased intracellular drug accumulation may underlie resistance. Topotecan, but not irinotecan, is a substrate for Pgp; however, compared with other substrates, such as etoposide or doxorubicin, topotecan is a relatively poor substrate. Nonetheless, the BCRP/xenobiotic exporter ABCG2/BCRP is overexpressed in cultured cells that have become resistant to irinotecan after exposure to camptothecins. Cell lines that lack carboxylesterase activity demonstrate resistance to irinotecan, but the liver and red blood cells may have sufficient carboxylesterase activity to convert irinotecan to the active metabolite SN-38. Camptothecin resistance also may result from decreased expression or mutation of topoisomerase I. A transient downregulation of topoisomerase I has been demonstrated following prolonged exposure to camptothecins in vitro and in vivo. Mutations leading to reduced topoisomerase I enzyme catalytic activity or DNA-binding affinity have been associated with experimental camptothecin resistance. Finally, exposure of cells to topoisomerase I-targeted agents upregulates topoisomerase II, an alternative enzyme for DNA strand passage.

Topotecan

ADME

Topotecan is approved for intravenous administration. An oral dosage form in development has a bioavailability of 30%–40% in patients with cancer. Topotecan exhibits linear pharmacokinetics, and it is rapidly eliminated from systemic circulation with a t_{1/2} of about 3.5–4.1 h. Only 20%–35% of the total drug in plasma is found to be in the active lactone form. Within 24 h, 30%–40% of the administered dose appears in the urine. Doses should be reduced in proportion to reductions in Cl_{cr}. Hepatic metabolism appears to be a relatively minor route of drug elimination. Plasma protein binding of topotecan is low (7%–35%), which may explain its relatively greater CNS penetration.

Therapeutic Uses

Topotecan is indicated for previously treated patients with ovarian and small cell lung cancer. Significant hematological toxicity limits its use in combination with other active agents in these diseases (e.g., cisplatin). The recently-extended dosing regimen of topotecan for ovarian cancer and small
cell lung cancer is a 30-min infusion for 5 consecutive days every 3 weeks. For the treatment of patients with cervical cancer in conjunction with cisplatin, topotecan is administered on days 1, 2, and 3, repeated every 21 days. The dose of topotecan should be reduced in patients with moderate renal dysfunction (CL_{cre} of 20–40 mL/min); topotecan should not be administered to patients with severe renal impairment (CL_{cre} < 20 mL/min). Hepatic dysfunction does not alter topotecan clearance and toxicity. A baseline neutrophil count greater than 1500 cells/mm² and a platelet count above 100,000 is necessary prior to topotecan administration.

**Adverse Effects**

The dose-limiting toxicity with all dosing schedules is neutropenia, with or without thrombocytopenia. The incidence of severe neutropenia at 1.5 mg/m² daily for 5 days every 3 weeks may be as high as 81%, with a 26% incidence of febrile neutropenia. In patients with hematological malignancies, GI side effects such as mucositis and diarrhea become dose limiting. Other less common and generally mild topotecan-related toxicities include nausea and vomiting, elevated liver transaminases, fever, fatigue, and rash.

**Irinotecan**

**ADME**

The conversion of irinotecan to its active metabolite SN-38 is mediated predominantly by carboxylesterases in the liver (see Figures 6–6 and 6–7). Although SN-38 can be measured in plasma shortly after beginning an intravenous infusion of irinotecan, the AUC of SN-38 is only about 4% of the AUC of irinotecan, suggesting that only a relatively small fraction of the dose is ultimately converted to the active form of the drug. Irinotecan exhibits linear pharmacokinetics. In comparison to topotecan, a relatively large fraction of both irinotecan and SN-38 are present in plasma as the biologically active intact lactone form. The t_{1/2} of SN-38 is 11.5 h, three times that of topotecan. CSF penetration of SN-38 in humans has not been characterized.

In contrast to topotecan, hepatic metabolism of irinotecan and SN-38 represents an important route of elimination for both. Oxidative metabolites have been identified in plasma, all of which result from CYP3A-mediated reactions directed at the bis-piperidine side chain. These metabolites are not significantly converted to SN-38. The total body clearance of irinotecan was found to be two times greater in patients with brain cancer taking antiseizure drugs that induce hepatic CYPs.

UGT1A1 glucuronidates the hydroxyl group at position C10 (resulting from cleavage of the bispiperidine promoiety), producing the inactive glucuronide metabolite SN-38G (see Figures 6–6 and 6–7). Biliary excretion appears to be the primary elimination route of irinotecan, SN-38, and metabolites, although urinary excretion also contributes (14%–37%). The extent of SN-38 glucuronidation inversely correlates with the risk of severe diarrhea after irinotecan therapy. UGT1A1 polymorphisms associated with familial hyperbilirubinemia syndromes may have a major impact on the clinical use of irinotecan. In patients treated with irinotecan, there is a positive correlation between baseline serum unconjugated bilirubin concentration and both severity of neutropenia and the AUC of irinotecan and SN-38. Severe irinotecan toxicity has been observed in patients with cancer with Gilbert syndrome, presumably due to decreased glucuronidation of SN-38. In patients with the syndrome, elevated levels of unconjugated bilirubin in the bloodstream are due to reduced activity of glucuronosyltransferase. The presence of bacterial glucuronidase in the intestinal lumen potentially can contribute to irinotecan GI toxicity by releasing unconjugated SN-38 from the inactive glucuronide metabolite.

**Therapeutic Uses**

Single-agent dosage of irinotecan is by weekly infusion for 4 of 6 weeks, with a higher dose given every 3 weeks. In patients with advanced colorectal cancer, irinotecan is used as first-line therapy in combination with fluoropyrimidines or as a single agent or in combination with cetuximab following failure of a 5FU/oxaliplatin regimen. It also has activity in small cell lung cancer. A irinotecan liposome injection in combination with 5FU and leucovorin was recently approved by the FDA for treatment of metastatic pancreatic cancer after disease progression following gemcitabine therapy.

**Adverse Effects**

The dose-limiting toxicity with all dosing schedules is delayed diarrhea (35%), with or without neutropenia. An intensive regimen of loperamide (see Chapter 49) reduces this incidence by more than half. However, once severe diarrhea occurs, standard doses of antidiarrheal agents tend to be ineffective. Diarrhea generally resolves within a week and, unless associated with fever and neutropenia, rarely is fatal.

The second most common irinotecan-associated toxicity is myelosuppression. Severe neutropenia occurs in 14%–47% of the patients treated with a schedule of administration every 3 weeks and is less frequently encountered amongst patients treated with the weekly schedule. Febrile neutropenia is observed in 3% of patients and may be fatal, particularly when associated with concomitant diarrhea. A cholestatic syndrome resulting from the inhibition of acylcholinesterase activity by irinotecan may occur within the first 24 h after irinotecan administration. Symptoms include acute diarrhea, diaphoresis, hypersalivation, abdominal cramps, visual accommodation disturbances, lacrimation, rhinorrhea, and, less often, asymptomatic bradycardia. These effects are short lasting and respond within minutes to atropine. Other common toxicities include nausea and vomiting, fatigue, vasodilation or skin flushing, mucositis, elevation in liver transaminases, and alopecia. There have been case reports of dyspnea and interstitial pneumonitis associated with irinotecan therapy.

**Antibiotics**

**Dactinomycin (Actinomycin D)**

Dactinomycins are chromopeptides isolated from Streptomyces soil bacteria. Most contain the same chromophore, the planar phenoazine actinomycin, which is responsible for their yellow-red color. The differences amongst naturally occurring actinomycins are confined to variations in the structure of the amino acids of the peptide side chains. Actinomycin D has beneficial effects in the treatment of solid tumors in children and choriocarcinoma in adult women.

**Mechanism of Action**

The capacity of actinomycins to bind to double-helical DNA is responsible for their biological activity and cytotoxicity. The planar phenozone ring intercalates between adjacent guanine-cytosine base pairs of DNA, while the polypeptide chains extend along the minor groove of the helix, resulting in a dactinomycin-DNA complex with stability sufficient to block the transcription of DNA by RNA polymerase. The DNA-dependent RNA polymerases are much more sensitive to the effects of dactinomycin than are the DNA polymerases. In addition, dactinomycin causes single-strand breaks in DNA, possibly through a free-radical intermediate or as a result of the action of topoisomerase II. Dactinomycin inhibits rapidly proliferating cells of normal and neoplastic origin and is amongst the most potent antitumor agents known.

**ADME**

Dactinomycin is administered by intravenous injection. Metabolism of the drug is minimal. The drug is excreted in both bile and urine and disappears from plasma with a terminal t_{1/2} of 36 h. Dactinomycin does not cross the blood-brain barrier.

**Therapeutic Uses**

Dactinomycin is given intravenously for 5 days, usually in the range of 10–15 μg/kg. If no manifestations of toxicity are encountered, additional courses may be given at intervals of 2–4 weeks, although weekly maintenance doses have been used. The main clinical use of dactinomycin is in the treatment of rhabdomyosarcoma and Wilms tumor in children, where it is curative in combination with primary surgery, radiotherapy, and other drugs, particularly vincristine and cyclophosphamide. Ewing, Kaposi, and soft-tissue sarcomas also respond. Dactinomycin and MTX form a curative therapy for choriocarcinoma.
Adverse Effects
Toxic manifestations include anorexia, nausea, and vomiting, usually beginning a few hours after administration. Hematopoietic suppression with pancytopenia may occur in the first week after completion of therapy. Proctitis, diarrhea, glossitis, cheilitis, and ulcerations of the oral mucosa are common; dermatological manifestations include alopecia, as well as erythema, desquamation, and increased inflammation and pigmentation in areas previously or concomitantly subjected to X-ray radiation. Severe injury may occur as a result of local drug extravasation; the drug is extremely corrosive to soft tissues.

Anthracyclines and Anthracenediones
Anthracyclines are derived from the fungus Streptomyces peucetius var. caesius. Idarubicin and epirubicin are analogues of the naturally produced anthracyclines doxorubicin and daunorubicin, differing only slightly in chemical structure, but having somewhat distinct patterns of clinical activity. Daunorubicin and idarubicin primarily have been used in acute leukemias, whereas doxorubicin and epirubicin display broader activity against solid tumors. These agents, which possess the potential for generating free radicals, cause an unusual and often-irreversible cardiomyopathy, the occurrence of which is related to the total dose of the drug. The structurally similar agent mitoxantrone has less cardiotoxicity and is useful against prostate cancer and AML and in high-dose chemotherapy.

Mechanisms of Action and Resistance
Anthracyclines and anthracediones can intercalate with DNA, directly affecting transcription and replication. More important is their capacity to form a heterotrimeric complex with topoisomerase II and DNA. Topoisomerase II produces double-strand breaks at the 5′-phosphate backbone, allowing strand passage and uncoiling of supercoiled DNA. Following strand passage, topoisomerase II religates the DNA strands; this enzyme function is essential for DNA replication and repair. Formation of the ternary complex with anthracyclines or with etoposide inhibits the religation of the broken DNA strands, leading to apoptosis. Defects in DNA double-strand break repair sensitize cells to damage by these drugs, while altered DNA damage-sensing and DNA repair capacity may contribute to resistance.

The quinone moieties of anthracyclines can form radical intermediates that react with O₂ to produce superoxide anions radicals, which can generate H₂O₂ and •OH that attack DNA and oxidize DNA bases, leading to apoptosis (Serrano et al., 1999). The production of free radicals is significantly stimulated by the interaction of doxorubicin with iron. Enzymatic defenses such as superoxide dismutase and catalase protect cells against the toxicity of the anthracyclines, and these defenses can be augmented by exogenous antioxidants such as α-tocopherol or by the iron chelator deferoxoxanone, which protects against cardiac toxicity. Multidrug resistance is observed in tumor cell populations exposed to anthracyclines. Anthracyclines also are exported from tumor cells by members of the MRP transporter family and by ABCG2 (BCRP). Other biochemical changes in resistant cells include increased glutathione peroxidase activity, decreased activity or mutation of topoisomerase II, and enhanced ability to repair DNA strand breaks.

ADME
Daunorubicin, doxorubicin, epirubicin, and idarubicin are administered intravenously and are cleared by a complex pattern of hepatic metabolism and biliary excretion. Each anthracycline is converted to an active alcohol intermediate that plays a variable role in the therapeutic activity. The plasma disappearance curves for doxorubicin and daunorubicin are multiphasic, with a terminal t₁/2 of 30 h. Idarubicin has a t₁/2 of 15 h, and its active metabolite, idarubicinol, has a t₁/2 of 40 h. The drugs rapidly enter the heart, kidneys, lungs, liver, and spleen; they do not cross the blood-brain barrier. Clearance is delayed in the presence of hepatic dysfunction; at least a 50% initial reduction in dose should be considered in patients with elevated serum bilirubin levels.

Idarubicin and Daunorubicin
Therapeutic Use.
Idarubicin (~12 mg/m²/d for 3 days) is administered by slow intravenous injection (10–15 min) to avoid extravasation. Treatment is for 3 days. Idarubicin has less cardiotoxicity than the other anthracyclines. Daunorubicin (also named daunomycin or rubidomycin) is administered (at 24–45 mg/m²/d) intravenously for 3 days, with care to prevent extravasation. Total doses greater than 1000 mg/m² are associated with a high risk of cardiotoxicity. Daunorubicin may impart a red color to the urine. Daunorubicin and idarubicin are used in the treatment of patients with AML in combination with Ara-C.

Adverse Effects. Toxic effects of daunorubicin and idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, rash, and cardiac toxicity. Cardiac toxicity of anthracyclines can be acute or chronic and is described in detail next for doxorubicin.

Doxorubicin
Therapeutic Uses.
The dose (60–75 mg/m²) is administered as a single rapid intravenous infusion that is repeated after 21 days. A doxorubicin liposomal product is available for treatment of AIDS-related Kaposi sarcoma and is given intravenously in a dose of 20 mg/m² over 60 min and repeated every 3 weeks. The liposomal formulation also is approved for ovarian cancer for treatment at a dose of 50 mg/m² every 4 weeks and as a treatment of multiple myeloma (in conjunction with bortezomib), where it is given as a 30- to 45-mg/m² dose on day 4 each 21-day cycle. Patients should be advised that the drug may impart a red color to the urine. Doxorubicin is effective in malignant lymphomas. In combination with cyclophosphamide, vinca alkaloids, and other agents, it is an important ingredient for the successful treatment of lymphomas. It is a valuable component of various regimens of chemotherapy for adjuvant and metastatic carcinoma of the breast. The drug also is beneficial in pediatric and adult sarcomas, including osteogenic, Ewing, and soft-tissue sarcomas.

Adverse Effects. Toxities of doxorubicin and idarubicin include bone marrow depression, stomatitis, alopecia, GI disturbances, rash, and cardiac toxicity. Cardiac toxicity of anthracyclines can be acute or chronic and is described in detail next for doxorubicin.
Chronic, cumulative, dose-related toxicity (usually total doses of ≥ 550 mg/m²) progressing to congestive heart failure. The mortality rate in patients with congestive heart failure approaches 50%. The risk of cardiomyopathy increases markedly with dose; estimates run as high as 20% at total doses of 550 mg/m² (a total dose limit of 300 mg/m² is advised for pediatric cases). These total dosages should be exceeded only under exceptional circumstances or with the concomitant use of dexrazoxane, a cardioprotective iron-chelating agent (Swain et al., 1997). Cardiac irradiation, administration of high doses of cyclophosphamide or another anthracycline, or concomitant trastuzumab increases the risk of cardiac toxicity (Slamon et al., 2001). Late-onset cardiac toxicity, with congestive heart failure years after treatment, may occur in both pediatric and adult populations. In children treated with anthracyclines, there is a 3- to 10-fold elevated risk of arrhythmias, congestive heart failure, and sudden death in adult life. Concomitant administration of dexrazoxane may reduce troponin T elevations and may begin in the days following drug infusion and is characterized by severe disturbances in impulse conduction and frank congestive heart failure, often associated with pericardial effusion.

Podophyllotoxin Derivatives

Podophyllotoxin Derivatives

Two synthetic derivatives of podophyllotoxins have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin disease, and large cell lymphomas. These derivatives are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin, etoposide and teniposide have no effect on the blood-brain barrier. Teniposide is available for treatment of refractory ALL in children and is synergistic with cytarabine. Teniposide is administered or decreased expression of topoisomerase II, or (3) mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe et al., 1993).

Etoposide

Etoposide

ADME

Oral administration of etoposide results in variable absorption that averages about 50%. After intravenous injection, there is a biphasic pattern of clearance with a terminal $t_1/2$ of about 6–8 h in patients with normal renal function. Approximately 40% of an administered dose is excreted intact in the urine. In patients with compromised renal function, dosage should be reduced in proportion to the reduction in $\text{Cl}_{\text{Cr}}$. In patients with advanced liver disease, increased toxicity may result from a low serum albumin (decreased drug binding) and elevated bilirubin (which displaces etoposide from albumin); guidelines for dose reduction in this circumstance have not been defined. Drug concentrations in the CSF average 1%–10% of those in plasma.

Therapeutic Uses

The intravenous dose of etoposide for testicular cancer in combination therapy (with bleomycin and cisplatin) is 50–100 mg/m² for 5 days or 100 mg/m² on alternate days for three doses. For small cell carcinoma of the lung, the dosage in combination therapy (with cisplatin) is 100–200 mg/m²/d intravenously for 3 days. Cycles of therapy usually are repeated every 3–4 weeks. After relapse, oral administration of 50 mg/m²/d for 21 days is one treatment option. When given intravenously, the drug should be administered slowly over a 30- to 60-min period to avoid hypotension and bronchospasm, which likely result from the additives used to dissolve etoposide.

Etoposide is also active against non-Hodgkin lymphomas, acute nonlymphocytic leukemia, and Kaposi sarcoma associated with AIDS. Etoposide has a favorable toxicity profile for dose escalation in that its primary acute toxicity is myelosuppression. In combination with ifosfamide and carboplatin, it is frequently used for high-dose chemotherapy in total doses of 1500–2000 mg/m².

Adverse Effects

The dose-limiting toxicity of etoposide is leukopenia (nadir at 10–14 days, recovery by 3 weeks). Thrombocytopenia occurs less often and usually is not severe. Nausea, vomiting, stomatitis, and diarrhea complicate treatment in about 15% of patients. Alopecia is common but reversible. Hepatic toxicity is particularly evident after high-dose treatment. For both etoposide and teniposide, toxicity increases in patients with decreased serum albumin, an effect related to decreased protein binding of the drug. A disturbing complication of etoposide therapy is the development of an unusual form of acute nonlymphocytic leukemia with a translocation in chromosome 11q23. At this locus is a gene (the MLL gene) that regulates the proliferation of pluripotent stem cells. The leukemic cells have the cytological appearance of acute monocytic or monomyelocytic leukemia in adults, the drug is given in a daily dose of 12 mg/m² for 3 days with cytarabine. It also is used in advanced hormone-resistant prostate cancer in a dose of 12–14 mg/m² every 21 days.

Epipodophyllotoxins

Epipodophyllotoxins

Podophyllotoxin Derivatives

Two synthetic derivatives of podophyllotoxins have significant therapeutic activity in pediatric leukemia, small cell carcinomas of the lung, testicular tumors, Hodgkin disease, and large cell lymphomas. These derivatives are etoposide (VP-16-213) and teniposide (VM-26). Although podophyllotoxin binds to tubulin, etoposide and teniposide have no effect on microtubular structure or function at usual concentrations.

Mechanisms of Action and Resistance

Etoposide and teniposide form ternary complexes with topoisomerase II and DNA and prevent resealing of the break that normally follows topoisomerase binding to DNA. The enzyme remains bound to the free end of the broken DNA strand, leading to an accumulation of DNA breaks and cell death. Cells in the S and G, phases of the cell cycle are most sensitive to etoposide and teniposide. Resistant cells demonstrate (1) amplification of the MDRI gene that encodes the Pgp drug efflux transporter, (2) mutation or decreased expression of topoisomerase II, or (3) mutations of the p53 tumor suppressor gene, a required component of the apoptotic pathway (Lowe et al., 1993).
by intravenous infusion for 5 days or twice weekly. The drug has limited utility and is given primarily for acute leukemia in children and monocyte leukemia in infants, as well as globlastoma, neuroblastoma, and brain metastases from small cell carcinomas of the lung. Myelosuppression, nausea, and vomiting is its primary toxic effects.

**Drugs of Diverse Mechanisms of Action**

**Bleomycin**

The bleomycins, a unusual group of DNA-cleaving antibiotics, are fermentation products of Streptomyces verticillus, comprising a family of peptide polyketides. The drug currently employed clinically is a mixture of two copper-chelating peptides, bleomycins A₂ and B₁, that differ only in their terminal amino acid. Because their toxicities do not overlap with those of other cytotoxic drugs and because of their unique mechanism of action, bleomycin maintains an important role in treating Hodgkin disease and testicular cancer.

**Mechanisms of Action and Resistance**

Bleomycin's cytotoxicity results from its capacity to cause oxidative damage to the deoxyribose of thymidylate and other nucleotides, leading to single- and double-stranded breaks in DNA; the exact mechanism is unresolved. Bleomycin causes accumulation of cells in the G₂ phase of the cell cycle, and many of these cells display chromosomal aberrations, including chromatid breaks, gaps, fragments, and translocations. Bleomycin cleaves DNA by generating free radicals. In the presence of O₂ and a reducing agent, the metal-drug complex becomes activated and functions as a ferrous oxidase, transferring electrons from Fe²⁺ to molecular oxygen to produce oxygen radicals. Metallobleomycin complexes can be activated by reaction with the flavin enzyme, NADPH-CYP450 reductase. Bleomycin binds to DNA, and the activated complex generates free radicals that are responsible for abstraction of a proton at the 3° position of the deoxyribose backbone of the DNA chain, opening the deoxyribose ring and generating a strand break in DNA. An excess of breaks generates cell death.

Bleomycin is degraded by a specific hydrolase found in various normal tissues, including liver. Hydrolase activity is low in skin and lung, perhaps contributing to the serious toxicity. Some bleomycin-resistant cells contain high levels of hydrolase activity. In other cell lines, resistance has been attributed to decreased uptake, repair of strand breaks, or drug inactivation by thiols or thiol-rich proteins.

**ADME**

Bleomycin is administered intravenously, intramuscularly, or subcutaneously or instilled into the bladder for local treatment of bladder cancer. Having a high molecular mass, bleomycin crosses the blood-brain barrier poorly. The elimination t₁/₂ is about 3 h. About two-thirds of the drug is excreted intact in the urine. Concentrations in plasma are greatly elevated in patients with renal impairment, and doses of bleomycin should be reduced in the presence of a Clₐ less than 60 mL/min.

**Therapeutic Uses**

Bleomycin is given weekly or twice weekly by the intravenous, intramuscular, or subcutaneous route. A test dose of 2 units or less is recommended for patients with lymphoma. Myriad regimens are employed clinically, with bleomycin doses expressed in units. Total doses exceeding 250 mg should be given with caution, and usually only in high-risk testicular cancer treatment, because of a marked increase in the risk of pulmonary toxicity. Bleomycin also may be instilled into the pleural cavity in doses of 5–60 mg to ablate the pleural space in patients with malignant effusions. Bleomycin is highly effective against germ cell tumors of the testis and ovary. In testicular cancer, it is curative when used with cisplatin and vinblastine or cisplatin and etoposide. It is a component of the standard curative ABVD regimen for Hodgkin disease.

**Adverse Effects**

Because bleomycin causes little myelosuppression, it has significant advantages in combination with other cytotoxic drugs. However, it does cause a constellation of cutaneous toxicities, including hyperpigmentation, hyperkeratosis, erythema, even ulceration, and rarely, Raynaud phenomenon. Skin lesions may recur when patients are treated with other antineoplastic drugs. Rarely, bleomycin causes a flagellate dermatitis consisting of bands of pruritic erythema on the arms, back, scalp, and hands; this rash responds readily to topical corticosteroids.

The most serious adverse reaction to bleomycin is pulmonary toxicity, which begins with a dry cough, fine rales, and diffuse basilar infiltrates on X-ray and may progress to life-threatening pulmonary fibrosis. Approximately 5%–10% of patients receiving bleomycin develop clinically apparent pulmonary toxicity, and about 1% die of this complication. Most who recover experience a significant improvement in pulmonary function, but fibrosis may be irreversible. Pulmonary function tests are not of predictive value for detecting early onset of this complication. The risk of pulmonary toxicity is related to total dose, with a significant increase in risk in total doses greater than 250 mg and in patients more than 40 years of age, in those with a Clₐ less than 80 mL/min, and in those with underlying pulmonary disease; single doses of 30 mg/m² or more are also associated with an increased risk of pulmonary toxicity. Administration of high O₂ concentrations during anesthesia or respiratory therapy may aggravate or precipitate pulmonary toxicity in patients previously treated with the drug. There is no known specific therapy for bleomycin lung injury except for symptomatic management and standard pulmonary care. Steroids are of variable benefit, with greatest effectiveness in the earliest inflammatory stages of the lesion.

Other toxic reactions to bleomycin include hyperthermia, headache, nausea and vomiting, and a peculiar acute fulminant reaction observed in patients with lymphomas. This reaction is characterized by profound hyperthermia, hypotension, and sustained cardiorespiratory collapse; it does not appear to be a classical anaphylactic reaction and may be related to release of an endogenous pyrogen. This reaction has occurred in about 1% of patients with lymphomas or testicular cancer.

**Mitomycin**

Mitomycin has limited clinical utility, having been replaced by less toxic and more effective drugs, with the exception of the use in patients with anal cancers, for which it is potentially curative.

**Mechanisms of Action and Resistance**

After intracellular enzymatic or spontaneous chemical alteration, mitomycin becomes a bifunctional or trifunctional alkylating agent. The drug inhibits DNA synthesis and cross-links DNA at the N6 position of adenine and at the O6 and N7 positions of guanine. Attempts to repair DNA lead to strand breaks. Mitomycin is a potent radiosensitizer, teratogen, and carcinogen in rodents. Resistance has been ascribed to deficient activation, intracellular inactivation of the reduced Q form, and Pgp-mediated drug efflux.

**ADME**

Mitomycin is administered intravenously. It has a t₁/₂ of 25–90 min. The drug distributes widely throughout the body but is not detected in the CNS. Inactivation occurs by hepatic metabolism or chemical conjugation with sulhydryls. Less than 10% of the active drug is excreted in the urine or bile.

**Therapeutic Uses**

Mitomycin is administered as a single bolus (6–20 mg/m²) every 6–8 weeks. Dosage should be modified based on hematological recovery. Mitomycin also may be used by direct instillation into the bladder to treat superficial transitional cell carcinomas. Mitomycin is used in combination with...
5FU and cisplatin for the treatment of anal cancer. Mitomycin is used off label (as an extemporaneously compounded eye drop) as an adjunct to surgery to inhibit wound healing and reduce scarring.

**Adverse Effects**
The major toxic effect is myelosuppression, characterized by marked leukopenia and thrombocytopenia; after higher doses, maximal suppression may be delayed and cumulative, with recovery only after 6–8 weeks of pancytopenia. Nausea, vomiting, diarrhea, stomatitis, rash, fever, and malaise are also observed. Patients who have received more than 50 mg/m2 total dose may acutely develop hemolysis, neurological abnormalities, interstitial pneumonia, and glomerular damage resulting in renal failure. The incidence of renal failure increases to 28% in patients who receive total doses of 70 mg/m2 or more. There is no effective treatment of the disorder. It must be recognized early, and mitomycin must be discontinued immediately. Mitomycin causes interstitial pulmonary fibrosis; total doses greater than 30 mg/m2 have infrequently led to congestive heart failure. Mitomycin may potentiate the cardiotoxicity of doxorubicin.

**Mitotane**
Mitotane (o,p'-DDD), a compound chemically similar to the insecticides DDT and DDDD, is used in the treatment of adrenal cortex carcinoma. The mechanism of action of mitotane has not been elucidated, but its relatively selective destruction of adrenocortical cells, normal or neoplastic, is well established. Administration of the drug causes a rapid reduction in the levels of adrenocorticosteroids and their metabolites in blood and urine, a response that is useful in both guiding dosage and following the course of hyperadrenocorticism (Cushing syndrome) resulting from an adrenal tumor or adrenal hyperplasia. It does not damage other organs.

**ADME**
Approximately 40% of mitotane is absorbed after oral administration. Plasma concentrations of mitotane are still measurable for 6–9 weeks following discontinuation of therapy. Although the drug is found in all tissues, fat is the primary site of storage. A water-soluble metabolite of mitotane found in the urine constitutes 25% of an oral or parenteral dose. About 60% of an oral dose is excreted unchanged in the stool.

**Therapeutic Uses**
Mitotane initial daily oral doses are 2–6 g, usually in three or four divided portions. The maximal tolerated dose may vary from 2 to 16 g/d. Treatment should continue for at least 3 months; if beneficial effects are observed, therapy should be maintained indefinitely. Spironolactone should not be administered concomitantly because it interferes with the adrenal suppression produced by mitotane. Treatment with mitotane is indicated for the palliation of inoperable adrenocortical carcinoma, producing symptomatic benefit in 30%–50% of such patients.

**Adverse Effects**
Although the administration of mitotane produces anorexia and nausea in most patients, somnolence and lethargy in about 34%, and dermatitis in 15%–20%, these effects do not contraindicate the use of the drug at lower doses. Because this drug damages the adrenal cortex, administration of replacement doses of adrenocorticosteroids is necessary.

**Trabectedin**
Trabectedin is derived from the marine invertebrate tunicate Ecteinascidin turbinata. Trabectedin is an alkylating drug that binds to the minor groove of DNA, allowing the alkylation of the N2 position of guanine and bending the helix toward the major groove. The bulky DNA adduct is recognized by the transcription-coupled nucleotide excision-repair (NER) complex, and these proteins initiate attempts to repair the damaged strand, converting the adduct to a double-stranded break. Trabectedin has particular cytotoxic effects on cells that lack components of the Fanconi anemia complex or those that lack the activity to repair double-strand DNA breaks through homologous recombination (Soares et al., 2007). Unlike cisplatin and other DNA adduct-forming drugs, the activity of trabectedin requires the presence of intact components of NER, including XPG, which may be important for initiation of single breaks and attempts at adduct removal.

**ADME**
Trabectedin is administered as a 24-h infusion of 1.3 mg/m2 every 3 weeks. It is administered with dexamethasone, 4 mg twice daily, starting 24 h before drug infusion to diminish hepatic toxicity. The drug is slowly cleared by CYP3A4, with a plasma t1/2 of about 24–40 h.

**Therapeutic Uses**
Trabectedin is approved for the treatment of patients with unresectable or metastatic liposarcoma or leiomyosarcoma after an anthracycline-containing regimen and is under study as an orphan drug for the treatment of patients with ovarian and pancreatic cancer.

**Adverse Effects**
Without dexamethasone pretreatment, trabectedin causes significant hepatic enzyme elevations and fatigue in at least one-third of patients. With the steroid, the increases in transaminase are less pronounced and rapidly reversible. Other toxicities include mild myelosuppression and, rarely, rhabdomyolysis.

**l-Asparaginase**
Malignant lymphoid cells depend on exogenous sources of l-asparagine. Thus, l-asparaginase (l-ASP) has become a standard agent for treating ALL.

**Mechanism of Action**
Most normal tissues synthesize l-asparagine in amounts sufficient for protein synthesis, but lymphocytic leukemias lack adequate amounts of asparagine synthase and derive the required amino acid from plasma. l-ASP, by catalyzing the hydrolysis of circulating asparagine to aspartic acid and ammonia, deprives these malignant cells of asparagine, leading to cell death. l-ASP is used in combination with other agents, including MTX, doxorubicin, vincristine, and prednisone, for the treatment of ALL and high-grade lymphomas. Resistance arises through induction of asparagine synthetase in tumor cells.

**ADME and Therapeutic Use**
Asparaginase is given intramuscularly or intravenously. After intravenous administration, *Escherichia coli*–derived l-ASP has a clearance rate from plasma of 0.035 mL/min/kg, a volume of distribution that approximates the volume of plasma in humans, and a t1/2 of 1 day. The enzyme is given in doses of 6000–10,000 IU every third day for 3–4 weeks. Pegaspargase, a preparation in which the enzyme is conjugated to 5000-Da units of monomethoxy polyethylene glycol, has a much longer plasma t1/2 (6–7 days); it is administered intramuscularly every 14 days, producing rapid and complete depletion of plasma and tumor cell asparagine for 21 days in most patients. Pegaspargase has much reduced immunogenicity (<20% of patients develop antibodies) and has been approved for first-line ALL therapy.

Intermittent dosage regimens and longer durations of treatment increase the risk of inducing hypersensitivity. In hypersensitive patients, neutralizing antibodies inactivate l-ASP. Not all patients with neutralizing antibodies experience clinical hypersensitivity, although the enzyme may be inactivated and therapy may be ineffective. In previously untreated ALL, pegaspargase produces more rapid clearance of lymphoblasts from bone marrow than does the *E. coli* preparation and circumvents the rapid antibody-mediated clearance seen with *E. coli*.
enzyme in relapsed patients. Asparaginase preparations only partially deplete CSF asparagine.

**Adverse Effects**
The 1-ASP toxicities result from its antigenicity as a foreign protein and its inhibition of protein synthesis. Hypersensitivity reactions, including urticaria and full-blown anaphylaxis, occur in 5%–20% of patients and may be fatal. In these patients, pegaspargase is a safe and effective alternative. So-called silent enzyme inactivation by antibodies occurs in a higher percentage of patients than overt hypersensitivity and may be associated with a negative clinical outcome, especially in high-risk patients with ALL.

Other toxicities result from inhibition of protein synthesis in normal tissues (e.g., hyperglycemia due to insulin deficiency, clotting abnormalities due to deficient clotting factors, hypertriglyceridemia due to effects on lipoprotein production, hypoalbuminemia). Pancreatitis also has been observed. The clotting problems may take the form of spontaneous thrombosis or, less frequently, hemorrhagic episodes. Brain magnetic resonance imaging studies should be considered in patients treated with 1-ASP who present with seizures, headache, or altered mental status. Intracranial hemorrhage in the first week of 1-ASP treatment is an infrequent but devastating complication. 1-ASP also suppresses immune function. 1-ASP terminates the antitumor activity of MTX when given shortly after the antimetabolite. By lowering serum albumin concentrations, 1-ASP may decrease protein binding and accelerate plasma clearance of other drugs.

**Hydroxyurea**

Hydroxyurea inhibits RNR and has unique and diverse biological effects as an antileukemic drug, radiation sensitizer, and an inducer of HbF in patients with sickle cell disease. It is orally administered, and its toxicity is modest and limited to myelosuppression.

**Mechanisms of Action and Resistance**

Hydroxyurea inhibits the enzyme ribonucleotide reductase (RNR), which catalyzes the reductive conversion of ribonucleotides to deoxyribonucleotides, a rate-limiting step in the biosynthesis of DNA. HU binds iron molecules that are essential for activation of a tyrosyl radical in the catalytic subunit of RNR. The drug is specific for the S phase of the cell cycle, during which RNR concentrations are maximal. HU produces arrest at or near the G1-S interface through both p53-dependent and -independent mechanisms. Because cells are highly sensitive to irradiation at the G1-S boundary, HU and irradiation cause synergistic antitumor effects. Through depletion of deoxyribonucleotides, HU potentiates the antiproliferative effects of DNA-damaging agents such as cisplatin, alkylating agents, or topoisoerase II inhibitors and facilitates the incorporation of anti-metabolites such as Ara-C, gemcitabine, and fludarabine into DNA. It also promotes degradation of the p21 cell-cycle checkpoint and thereby enhances the effects of HDAC inhibitors in vitro (Kramer et al., 2008).

Hydroxyurea is the primary drug for improving control of sickle cell (HBS) disease in adults and for inducing HbF in patients with thalassemia HbC and HbC/S. It reduces vaso-occlusive events, painful crises, hospitalizations, and the need for blood transfusions in patients with sickle cell disease. The mechanism of stimulated HbF production is uncertain. HU stimulates NO production, causing nitrosylation of low-molecular-weight GTPases, a process that stimulates γ-globin production in erythroid precursors. Another property of HU that may be therapeutically relevant is its capacity to reduce t-selectin expression and thereby to reduce adhesion of red cells and neutrophils to vascular endothelium. Also, by suppressing the production of neutrophils, it decreases their contribution to vascular occlusion. Tumor cells become resistant to HU through increased synthesis of the catalytic subunit of RNR, thereby restoring enzyme activity.

**Adverse Effects**

Leukopenia, anemia, and occasionally thrombocytopenia are the major toxic effects; recovery of the bone marrow is prompt if the drug is discontinued for a few days. Other adverse reactions include a desquamative interstitial pneumonitis, GI disturbances, mild dermatological reactions, and, more rarely, stomatitis, alopecia, and neurological manifestations. Increased skin and fingernail pigmentation may occur, as well as painful leg ulcers, especially in elderly patients or in those with renal dysfunction. HU does not increase the risk of secondary leukemia in patients with myeloproliferative disorders or sickle cell disease. It is a potent teratogen in animals and should not be used in women with childbearing potential.

**Retinoids**

One of the hallmarks of malignant transformation is a block in differentiation. A number of chemical entities (vitamin D and its analogues, retinoids, benzamides and other inhibitors of HDAC [see Chapter 67], various cytotoxic and biological agents, and inhibitors of DNA methylation) can induce differentiation in tumor cell lines. The most important of these for cancer treatment are retinoids, in particular tretinoin (ATRA), which induces a high rate of complete remission in patients with APL as a single agent and, in combination with anthracyclines, cures most patients with this disease. The biology and pharmacology of retinoids are discussed in detail in Chapter 70.

**Tretinoin (ATRA)**

**Mechanism of Action.** Under physiological conditions, the RARA dimerizes with the retinoid X receptor to form a complex that binds ATRA tightly. ATRA binding displaces a repressor from the transcriptional complex and alters the expression of genes that control differentiation of cells of multiple lineages. Most APLs are characterized by a chromosomal translocation of the RARA gene on chr17 and fusion with the PML on
As O

08/09/17   1:33 PM

AsO₃, known as ATO, is a highly effective treatment of relapsed APL, producing complete responses in more than 85% of such patients. The chemistry and toxicity of arsenic are considered in Chapter 71.

Mechanism of Action

The basis for ATO's antitumor activity remains uncertain. APL cells have high levels of ROS and are quite sensitive to further ROS induction. ATO inhibits thiorodoxin reductase and thereby generates ROS. It inactivates glutathione and other sulfhydryls that scavenge ROS and thereby aggravates ROS damage. Cells exposed to ATO also upregulate p53, Jun kinase, and caspases associated with the intrinsic pathway of apoptosis and downregulate antiapoptotic proteins such as bcl-2 (Figure 13–15). ATO's cytotoxic effects are antagonized by cell survival signals emanating from activation of components of the P13 kinase cell survival pathway, including PKB, S6 kinase, and mTOR (Figures 3–16 and 67–4). ATO also induces differentiation of leukemic cell lines in experimental and human leukemias.

ADME

Arsenic trioxide is well absorbed orally but in cancer treatment is administered as a 2-h daily intravenous infusion in dosages of 0.15 mg/kg/d for up to 60 days, until remission is documented. The drug enters cells via one of several glucose transporters. The primary mechanism of elimination is through enzymatic methylation. Multiple methylated metabolites (Figure 71–9) form rapidly and are excreted in urine. Less than 20% of administered drug is excreted unchanged in the urine. No dose reductions are indicated for hepatic or renal dysfunction.

Adverse Effects

Pharmacological doses of ATO are well tolerated. Patients may experience reversible side effects, including hyperglycemia, hepatic enzyme elevations, fatigue, dysesthesias, and light-headedness. Fewer than 10% of patients experience a leukocyte maturation syndrome similar to that seen with ATRA, including pulmonary distress, effusions, and mental status changes. Oxygen, corticosteroids, and temporary discontinuation of ATO lead to full reversal of this syndrome. Lengthening of the QT interval on the electrocardiogram occurs in 40% of patients, but rarely do patients develop torsade de pointes. Simultaneous treatment with other QT-prolonging drugs should be avoided. Monitoring of serum electrolytes and repletion of serum K⁺ in patients with hypokalemia are precautionary measures in patients receiving ATO therapy. In patients exhibiting a significantly prolonged QT (>470 ms), treatment should be suspended, K⁺ supplemented, and therapy resumed only if the QT returns to normal.

|                            |                                                          | • Leucovorin can reverse toxic effects; used as “rescue” in high-dose therapy                 |
|                            |                                                          | • Glucarpidase, a methotrexate-cleaving enzyme, is approved to treat toxicity                  |
|                            |                                                          | • ↓ Dose in renal insufficiency                                                                |

| Pemetrexed                | • Metastatic lung cancer                                 | • Similar effects and side effects as methotrexane                                           |
|                          |                                                          | • Attenuate toxicity with folate and Vit B12 supplementation                                   |

### Pyrimidine Analogues

| 5-Fluorouracil (5FU)     | • Breast, colon, esophageal, stomach, anal cancer        | • Intravenous administration                                                                |
| Thymidylate synthase inhibitor | • In FOLFOX or FOLFIRINOX combination to treat pancreatic or colorectal cancer | • Nausea, mucositis, diarrhea, myelosuppression, hand-foot syndrome                         |
|                          | • Combined with cisplatin in head and neck cancer        | • Combined with leucovorin to enhance efficacy                                               |
|                          | • Premalignant skin lesion (topical)                    | • Enhanced toxicity with DPD deficiency; may rescue with uridine                            |

| Capecitabine             | • Breast, colorectal cancer                              | • Orally administered prodrug of SFU                                                        |
| Thymidylate synthase inhibitor | • Oral absorption incomplete, thus intravenous administration | • Similar adverse effects as SFU; hand and foot syndrome more frequent than with SFU       |

| Cytarabine (cytosine arabinoside) | • Acute myelogenous and acute lymphocytic leukemia; non-Hodgkin lymphoma | • Intravenous administration                                                                |
| Interferes with base pairing in DNA; inhibits DNA polymerase |                                                          | • Myelosuppressive; can cause acute, severe leukopenia, thrombocytopenia, anemia             |
|                            |                                                          | • GI disturbances                                                                           |
|                            |                                                          | • Noncardiogenic pulmonary edema                                                           |
|                            |                                                          | • Dermatitis                                                                              |

| Gemcitabine (difluoro analogue of deoxycytidine) | • Pancreatic, ovarian, lung, bladder cancer | • Intravenous administration                                                              |
| Inhibits DNA polymerase; causes strand termination |                                                          | • Female and elderly patients clear the drug more slowly                                    |
|                            |                                                          | • Myelosuppression, hepatic toxicity                                                        |
|                            |                                                          | • Rare posterior leukoencephalopathy syndrome; sometimes interstitial pneumonitis            |
|                            |                                                          | • Radiosensitizer; should be used with caution in radiotherapy                             |

| 5-Azacytidine            | • Myelodysplasia                                         | • Subcutaneous or intravenous administration                                                |
|                          |                                                          | • Myelosuppression and mild GI symptoms                                                    |
|                          |                                                          | • After intravenous administration severe nausea possible                                   |

### Purine Analogues and Related Inhibitors

| 6-Mercaptopurine | • Acute lymphocytic and myelogenous leukemia; small cell non-Hodgkin lymphoma | • Oral absorption incomplete, thus intravenous administration                              |
| Inhibits purine nucleotide synthesis and metabolism | • Noncancer: Crohn disease, ulcerative colitis | • Reduce oral dose by 75% in patients receiving allopurinol; no adjustment needed for intravenous administration |

| Fludarabine | • Chronic lymphocytic leukemia | • Oral or intravenous administration                                                       |
| A chain terminator when incorporated into DNA; inhibits RNA function and processing | • Frequently myelosuppression                                                               |
|            | • Follicular B-cell lymphoma   | • Less frequent: nausea, vomiting; altered mental status; seizures                         |
|            | • Allogeneic bone marrow transplant | • Secondary myelodysplasia and acute leukemias                                               |
|            |                                 | • Adjust dose for renal dysfunction                                                         |
### Purine Analogues and Related Inhibitors (continued)

<table>
<thead>
<tr>
<th>Substance</th>
<th>Mechanism and Effects</th>
<th>Indications</th>
</tr>
</thead>
</table>
| Cladribine (mechanism as above) | Incorporated into DNA, produces strand breaks; inhibits conversion of ribo- to deoxyribonucleotides | • Hairy cell leukemia  
• Chronic lymphocytic leukemia  
• Low-grade lymphoma  
• CTCL, Waldenström macroglobulinemia  
• Intravenous administration  
|                           |                                                                                    | • Adjust dose for renal dysfunction  
• Myelosuppression, opportunistic infections, nausea, high fever, tumor lysis syndrome |
| Clofarabine (mechanism as above) | Incorporates into DNA, terminates DNA synthesis  
|                           |                                                                                    | • Acute myelogenous or lymphocytic leukemia  
• Intravenous administration  
• Adjust dose to creatinine clearance  
• Myelosuppression  
• Capillary leak syndrome: discontinue drug  
| Nelarabine (mechanism as above) | Incorporates into DNA, terminates DNA synthesis  
|                           |                                                                                    | • T-cell leukemia, lymphoma  
• Intravenous administration  
| Pentostatin (2′-deoxycoformycin) | Inhibits adenosine deaminase; causes immunodeficiency (T and B cells)  
|                           |                                                                                    | • Hairy cell leukemia; chronic lymphocytic leukemia; small cell non-Hodgkin lymphoma  
|                           |                                                                                    | • Intravenous administration  
• Adjust dose for renal dysfunction  
• Myelosuppression; GI symptoms, skin rashes, opportunistic infections  
• Renal, neurologic, pulmonary toxicity  

### Section III: Natural Products

#### Vinca Alkaloids: Inhibit tubulin polymerization and microtubule formation

<table>
<thead>
<tr>
<th>Substance</th>
<th>Mechanism and Effects</th>
<th>Indications</th>
</tr>
</thead>
</table>
| Vinblastine     | • Hodgkin and non-Hodgkin lymphoma  
• Breast, bladder, lung, testicular cancer  
• Kaposi sarcoma, neuroblastoma  
• Part of ABVD combination with doxorubicin (adriamycin, bleomycin, dacarbazine) for Hodgkin lymphoma | • Intravenous administration; extravasation causes irritation and ulceration  
• Reduce dose in patients with impaired liver function  
• Least neurotoxic Vinca alkaloid  
• Myelosuppressive (granulocytopenia)  
| Vinorelbine     | • Breast cancer  
• Non–small cell lung cancer  
|                | • Intravenous administration  
• Reduce dose in patients with impaired liver function  
• Intermediate neurotoxicity amongst the Vinca alkaloids  
• Myelosuppressive (granulocytopenia)  
| Vincristine     | • Acute lymphocytic leukemia; neuroblastoma; Wilms tumor; rhabdomyosarcoma; Hodgkin and non-Hodgkin lymphoma  
• Part of CHOP regimen: cyclophosphamide, doxorubicin (H), vincristine (O), prednisone | • Intravenous administration; extravasation causes irritation and ulceration  
• Reduce dose in patients with impaired liver function  
• Least myelosuppressive Vinca alkaloid  
|                | • Dose-limiting neurotoxicity  
• Better tolerated by children than adults  
| Eribulin        | • Breast cancer, liposarcoma  
|                | • Side effects overlap with vinca but less sensitive to extrusion by Pgp  

#### Taxanes: Stabilize microtubules, inhibit depolymerization

<table>
<thead>
<tr>
<th>Substance</th>
<th>Mechanism and Effects</th>
<th>Indications</th>
</tr>
</thead>
</table>
| Paclitaxel      | • Ovarian, breast, lung, prostate, bladder, head and neck cancer  
|                | • Intravenous administration  
• Metabolized by hepatic CYPs, ↓ dose in patients with hepatic dysfunction  
• Substrate of Pgp efflux pump  
• Myelosuppressive, alleviated by G-CSF  
• Peripheral neuropathy is dose limiting  
| Docetaxel       | • Same as above  
|                | • No effect on doxorubicin clearance  
• Pharmacokinetics similar to paclitaxel's  
• ↓ Neutropenia, ↓ neuropathy than paclitaxel  

#### Camptothecins: Inhibit topoisomerase I; DNA religation is inhibited: accumulation of single-strand breaks

<table>
<thead>
<tr>
<th>Substance</th>
<th>Mechanism and Effects</th>
<th>Indications</th>
</tr>
</thead>
</table>
| Topotecan       | • Ovarian cancer; small cell lung cancer  
|                | • Intravenous or oral administration  
• Reduce dose in patients with renal dysfunction  
• Neutropenia, GI side effects, nausea, vomiting  
| Irinotecan      | • Colorectal cancer; small cell lung cancer  
• Part of FOLFIRI or FOLFIRINOX combination for GI tumors  
|                | • Intravenous administration  
• Podrug activated in the liver; CYP substrate  
• Diarrhea and neutropenia  
• Acetylhincholinesterase inhibition results in cholinergic syndrome: treat with atropine  

#### Antibiotics

<table>
<thead>
<tr>
<th>Substance</th>
<th>Mechanism and Effects</th>
<th>Indications</th>
</tr>
</thead>
</table>
| Dactinomycin (actinomycin D) | Intercalates between GC base pairs of DNA  
|                           |                                                                                    | • Wilms tumor; rhabdomyosarcoma; Ewing, Kaposi, and other sarcoma; choriocarcinoma  
|                           |                                                                                    | • Intravenous administration; severe injury on extravasation  
• Nausea, vomiting; myelosuppression; GI side effects; erythema, inflammation of the skin

</tbody>
</table>

*For drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP1A2 and can then reduce efficacy or increase side effects.

*Embryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

### Bibliography

# Pathway-Targeted Therapies: Monoclonal Antibodies, Protein Kinase Inhibitors, and Various Small Molecules

Anton Wellstein, Giuseppe Giaccone, Michael B. Atkins, and Edward A. Sausville

## I. Growth Factors and Receptors in Cancer Cells
- Inhibitors of EGFR Function
- HER2/Neu Inhibitors
- Inhibitors of PDGF Receptor
- Hedgehog Pathway Inhibitors

## II. Intracellular Protein Kinases in Cancer Cells
- Inhibitors of RAF Kinase: Vemurafenib, Dabrafenib
- Inhibitors of MEK: Trametinib, Cobimetinib
- Inhibitors of Jak1 and Jak2
- Cyclin-Dependent Kinase 4/6 Inhibitors
- Bruton Tyrosine Kinase Inhibitor
- Inhibitors of the BCR-ABL Kinase
- Inhibitors of ALK
- Inhibitors of the PI3K/AKT/mTOR Pathway
- Multikinase Inhibitors

## III. Tumor Angiogenesis
- Inhibition of VEGF and the VEGFR Pathway
- Antiangiogenic Small-Molecule Kinase Inhibitors

## IV. Targeting the Immune System
- ImmuneCheckpoint Inhibitors
- Inhibitors of CTLA4
- Inhibitors of PD-1
- Antagonists of PD-1 Ligand 1
- Combination of Anti–PD-1 and Anti–CTLA-4
- Cytokines to Stimulate Immune Responses
- Cancer Vaccines
- Chimeric Antigen Receptor T Cells
- Future Challenges of Immunotherapy

## V. Other Targets
- Inhibitors of Poly(ADP-Ribose) Polymerase
- Bcl2 Inhibitors
- Thalidomide and Lenalidomide
- Proteasome Inhibitors
- CD20 Inhibitors
- Other Cell Surface Targets for Monoclonal Antibodies
- Monoclonal Antibody–Cytotoxin Conjugates
- Cytokines and Growth Factors
- Inhibitors of Histone Deacetylase

</table>
Development of targeted therapies for treating cancer relies on the continuing process of discovery of molecular changes that drive malignant progression of human cancers. A rapidly growing number of drugs are being developed to block oncogenic pathways that lead to dysregulated cancer cell growth and survival. Targeted therapy may be combined with classical cytotoxic cancer drugs described in Chapter 66 for improved efficacy. Growth factor receptors and downstream signaling molecules are amongst the most actively explored targets for cancer drug discovery. The drivers of cancer growth are oncogenic in malignant cells themselves (e.g., mutant receptors and kinases), the reaction of the tumor microenvironment (e.g., angiogenesis), and the escape of malignant cells from the host’s immune surveillance (Hanahan and Weinberg, 2011). The discussion of drugs in this chapter is organized into sections focusing on these drivers of cancer growth:

I. Growth factors and receptors in cancer cells
II. Intracellular kinases in cancer cells
III. Tumor-host interactions reflected in aberrant tumor angiogenesis
IV. Restoring immune recognition of cancer cells
V. Other drugs and targets that control cancer cell behavior

The primary tools for targeting oncogenic pathways are monoclonal antibodies that recognize cell surface or shed antigens (e.g., growth factor receptors or receptor ligands) and small molecules that can enter cells and engage intracellular targets, many of them kinases. These two classes of drugs have very different pharmacological properties (see Box).

### Inhibitors of Epidermal Growth Factor Receptor (EGFR) Function

#### Background

The EGFR belongs to the ErbB family of transmembrane receptor tyrosine kinases also known as ErbB1 or HER1 (human EGFR). EGFR is essential for the growth and differentiation of epithelial cells. Ligand binding to the extracellular domain of EGFR family members causes receptor dimerization and stimulates the protein tyrosine kinase activity of the intracellular domain, resulting in autophosphorylation of several Tyr residues located in the C-terminal tail of the receptor monomers. These phosphotyrosines provide interaction sites for a variety of adapter proteins, resulting in stimulation of signaling pathways, including MAPK, PI3K/Akt, and STAT pathways (see Figure 67–1).

Two separate classes of drugs that target the EGFR pathway are important in the therapy of solid tumors: protein tyrosine kinase inhibitors and inhibitors of extracellular ligand binding. EGFR TKIs (erlotinib, gefitinib, afatinib, osimertinib) bind to the intracellular kinase domain and inhibit the enzymatic function of an EGFR. Monoclonal antibodies (cetuximab, panitumumab, necitumumab) recognize the extracellular domain of the EGFR, inhibit ligand-induced signaling, and can elicit an immune response.

In epithelial cancers, overexpression of the EGFR is a common finding, and mutational activation of the EGFR (e.g., in 10%–40% of NSCLCs) creates a dependence on EGFR signaling. The most common EGFR mutations are in-frame deletions in exon 19 or leucine-to-arginine substitutions in exon 21 (see Figures 34–6 and 34–7).

#### Prognosis

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.

### Two Classes of Pathway-Targeted Cancer Drugs

1. **Monoclonal Antibodies:** Monoclonal antibodies kill tumor cells by blocking cell surface receptor function, by recruiting immune cells and complement to the antigen-antibody complex, and by modulating immune cell function. Also, they may be armed to carry toxins or radionuclides to the cells of interest, thereby enhancing their cytotoxic effects. A monoclonal antibody is generally specific for a single antigen, such as an epitope in a growth factor receptor; has a long plasma t1/2; and requires only intermittent parenteral administration.

   **The Naming of Monoclonal Antibodies:** Monoclonal antibodies names end with the syllable “mab” preceded by “mu” for fully human protein sequence, “zi” for human protein with the antigen-binding region from a mouse antibody, “xi” for a chimera consisting of human constant and mouse variable antibody domains, and “o” for entirely mouse protein sequences (Hansel et al., 2010; see Figures 34–6 and 34–7).

2. **Small Molecules:** Small molecules may attack the same targets as monoclonal antibodies but can exert their effect by entering cells. Small molecules often inhibit multiple enzymes with different selectivities and thus are likely to have a broader spectrum of targets and produce a broader spectrum of desired effects, off-target effects, and adverse effects than monoclonal antibodies. Many small-molecule drugs have elimination half-lives of 12 to 24 h and typically require at least daily oral administration. For small-molecule drugs that are metabolized by hepatic CYPs, the concomitant use of strong CYP inhibitors (e.g., ketoconazole, nefazodone, clarithromycin, gemfibrozil, cobicistat) or inducers (e.g., rifampin, phenytoin, carbamazepine, phenobarbital, St John’s wort) can lead to increased adverse effects due to reduced drug elimination or to reduced efficacy due to accelerated clearance. The small-molecule inhibitors mentioned in this chapter, mostly protein kinase inhibitors, bind with the syllable “ib.” More than 130 novel TKIs are currently being evaluated in different clinical phases (Neul et al., 2016).

### Protein Tyrosine Kinase Inhibitors of EGFR

#### Erlotinib

**Mechanism of Action.** Erlotinib is a reversible inhibitor of the EGFR tyrosine kinase, competitively inhibiting ATP binding at the active site of the kinase. Erlotinib has an IC50 of 2 nM for EGFR kinase activity. By comparison, for many protein kinases, the K_i for ATP at the substrate site is in the range of 20 μM.

**ADME.** Erlotinib is about 60% absorbed after oral administration. Peak plasma levels occur after 4 h. Erlotinib has a t1/2 of 36 h and is metabolized by CYP3A4 and to a lesser extent by CYPs 1A2 and 1A1.

**Therapeutic Uses.** Erlotinib is approved for treatment of patients with advanced or metastatic NSCLC after failure of platinum-based treatment. In newly diagnosed NSCLC, erlotinib is approved in patients with EGFR mutations only (Figure 67–1). Erlotinib in combination with gemcitabine is also approved for the treatment of patients with locally advanced, unresectable, or metastatic pancreatic cancer.

---

**A Note on Treatment Regimens**

Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologicals; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides two examples of therapeutic regimens that illustrate the complexity of current cancer drug therapy.
In treating cancers, the selection of the most appropriate treatment(s), dose, and dose intervals as well as the management of adverse effects requires specialized knowledge and a team effort. In addition, cancer treatment regimens are undergoing frequent updates due to findings in ongoing clinical trials. The availability of drugs with new mechanisms of action (e.g., immune checkpoint inhibitors), good target selectivity (e.g., kinase inhibitors), efficacy in specific cancers, and different adverse effect profiles permits the use of new drug combinations and regimens. The chapters on the pharmacotherapy of cancer focus on mechanism of action, ADME, and adverse effects, with less emphasis on treatment regimens. There are several excellent sources of up-to-date treatment information. The U.S. FDA provides authoritative information on approved drugs online (http://www.accessdata.fda.gov/scripts/cder/daf/). Detailed treatment guidelines for most cancers are available from the NCCN, an alliance of cancer centers that establishes evidence-based guidelines for cancer treatment. The NCCN guidelines are continuously updated to reflect new information that may alter clinical practice. The guidelines can be accessed online (https://www.nccn.org/professionals/physician_gls/f_guidelines.asp).

This table provides examples that illustrate the complexities of current treatment for two cancers: HER2+ breast cancer and advanced colorectal cancer.

### SAMPLE TREATMENT REGIMENS

Followed by

| Day 1: Pertuzumab 840 mg IV followed by 420 mg IV |
| Day 1: Trastuzumab 8 mg/kg IV followed by 6 mg/kg IV |
| Days 1, 8, and 15: Paclitaxel 80 mg/m² IV |
| Repeat cycle every 21 days for 4 cycles |
| Day 1: Trastuzumab 6 mg/kg IV |
| Repeat cycle every 21 days to complete 1 year of trastuzumab therapy |

Cardiac monitoring at baseline and 3-month intervals

### Advanced or Metastatic Colorectal Cancer RAS wild-type

**Oxaliplatin, leucovorin, 5FU (= FOLFOX) plus cetuximab**

| Day 1: Oxaliplatin 85 mg/m² IV over 2 h |
| Day 1: Leucovorin 400 mg/m² IV over 2 h |
| Days 1–3: 5FU 400 mg/m² IV bolus on day 1, then 1200 mg/m²/d × 2 days (total 2400 mg/m² over 46–48 h) IV continuous infusion |
| Repeat cycle every 2 weeks, plus |
| Cetuximab 400 mg/m² IV over 2 h for the first infusion, then 250 mg/m² IV over 60 min weekly. |
| OR |
| Day 1: Cetuximab 500 mg/m² IV over 2 h every 2 weeks |

**Gefitinib**

**Mechanism of Action.** Gefitinib inhibits the EGFR tyrosine kinase by competitive blockade of ATP binding with an IC₅₀ of 20–60 nM for the kinase activity.

**ADME.** Oral bioavailability is about 60%; peak plasma concentrations are achieved within 3–7 h. Absorption of gefitinib is not significantly altered by food but is reduced by drugs that cause elevations in gastric pH. Metabolism of gefitinib is predominantly via CYP3A4, with a terminal t₁/₂ of 41 h. Inducers of CYP3A4 activity decrease gefitinib plasma concentrations and efficacy; conversely, CYP3A4 inhibitors increase plasma concentrations.

**Therapeutic Uses.** Gefitinib is approved for treatment of patients with metastatic NSCLC with EGFR mutations (Figure 67–1).

**Adverse Effects and Drug Interactions.** Diarrhea and skin reactions occur in more than 20% of patients. In addition to pustular/papular rash,
Section VIII: Pharmacotherapy of Neoplastic Disease

**Resistance to Gefitinib, Erlotinib, and Afatinib**

The majority of tumors with activating mutations in the EGFR initially respond to these kinase inhibitors of the first (gefitinib, erlotinib) and second generation (afatinib). Eventually, however, the tumors progress. Approximately 60% of NSCLC acquire a second EGFR mutation in the so-called EGFR gatekeeper residue T790M (see Figure 67–1) that prevents binding of these inhibitors to the kinase domain. Osimertinib, a third-generation inhibitor designed to recognize the T790M-mutant EGFR, is described next. Other mechanisms of resistance include mutational activation of downstream signaling molecules such as KRAS or activation of parallel signaling pathways, for example, through MET amplification, EML4-ALK translocation (see Figure 67–2), and small cell lung cancer transformation. ALK and MET kinase inhibitors are described in material that follows (Smit and Baas, 2015).

**Osimertinib**

**Mechanism of Action.** Osimertinib is a third-generation, orally bioavailable, irreversible inhibitor of T790M-mutant EGFR, with an IC₅₀ value of 10 nM. The T790M gatekeeper mutation is often acquired after prior treatment with other EGFR kinase inhibitors (see previous discussion). Very sensitive detection methods can identify the presence of T790M in up to 30% of untreated patients, suggesting preexisting resistant subpopulations (see Chapter 65, Figure 65–3).

**ADME.** The mean t₁/₂ of osimertinib is 48 h. Osimertinib is a substrate of CYP3A4 and may necessitate an increase in the dose.

**Therapeutic Uses.** Osimertinib is approved for metastatic NSCLC that has progressed after prior EGFR TKI treatment and is positive for the EGFR T790M mutation. Genotyping of tumor biopsies for the T790M mutation in patients with metastatic NSCLC. However, with osimertinib treatment acquired resistance occurs, most commonly manifested by the appearance of a third mutation, C797S. The mutation of Cys²⁷⁷ to Ser²⁷⁷ prevents formation of the potency-conferring covalent bond of the inhibitor (Thress et al., 2015). Inhibitors of C797S-mutant EGFR are under development for combination treatment with an EGFR-targeted antibody (Jia et al., 2016). Response rates are greater than 60% in patients with metastatic NSCLC. However, with osimertinib treatment acquired resistance occurs, most commonly manifested by the appearance of a third mutation, C797S. The mutation of Cys²⁷⁷ to Ser²⁷⁷ prevents formation of the potency-conferring covalent bond of the inhibitor (Thress et al., 2015). Inhibitors of C797S-mutant EGFR are under development for combination treatment with an EGFR-targeted antibody (Jia et al., 2016).

**Adverse Effects and Drug Interactions.** The most common adverse effects after osimertinib treatment are diarrhea and skin rash; however, these are much less common and severe than for first- and second-generation inhibitors, presumably because the activity on wild-type EGFR is limited with third-generation inhibitors. Also observed are interstitial lung disease, QTc prolongation, and left ventricular dysfunction.

**Antibody Inhibitors of EGFRs**

**Cetuximab**

**Mechanism of Action.** Cetuximab is a recombinant, chimeric human/mouse IgG antibody that binds to the extracellular domain III of EGFR (Figure 67–1) and prevents ligand-dependent signaling and receptor dimerization, thereby blocking cell growth and survival signals. Cetuximab can also mediate ADCC against tumor cells that express high levels of EGFR.

**ADME.** Cetuximab exhibits nonlinear pharmacokinetics. A single loading dose of cetuximab intravenously is followed by weekly administration.

**Figure 67–1 Targeting the EGFR in cancer.** The extracellular portion of the EGFR contains the binding domains for growth factors that include EGF, TGF-α, and amphiregulin. Ligand binding to extracellular domains I and III induces conformational change and receptor dimerization through domains II and IV and activates intracellular signaling by cross-phosphorylation. The monoclonal antibodies cetuximab and panitumumab recognize the growth factor–binding domain and prevent ligand binding. The intracellular portion contains the tyrosine kinase activity and a C-terminal tail that recruits intracellular substrates after phosphorylation (see Chapter 3). EGFR mutations enhance downstream signaling, which provides a growth and survival advantage for cancer cells and confers sensitivity to treatment with TKIs gefitinib, erlotinib, and afatinib. The most common activating mutations are in-frame deletions in exon 19 (del 19) between E746 and A750 (~45%) and a missense mutation in exon 21 that leads to an L858R substitution (~40%). Lung cancers with these mutations are initially sensitive to the TKIs mentioned. Resistance develops, however, most commonly via the T790M substitution found in about 50% of resistant tumors. TKIs such as osimertinib have been developed for the treatment of cancers with the T790M mutation. Genotyping for mutations in the EGFR is used to select patients who will receive TKIs and help predict which patients with lung cancer may respond best to some therapies. Numbers shown are amino acid positions in the EGFR protein.
Extracellular binding of agonist ligands to transmembrane growth factor receptors causes receptor dimerization and activation of a C-terminal protein kinase that initiates intracellular signaling cascades that regulate gene expression and control cancer cell proliferation, apoptosis, metabolism, and metastasis. Crosstalk between cancer cells and the host stroma (including the vasculature and immune cells) is modulated through the release of angiogenic factors and the expression of immune checkpoint proteins. Cancer cell signaling can be altered through increased expression of receptors (e.g., HER2) or ligands, activating mutations in receptors (e.g., ALK, EGFR, FGFR) or in intracellular kinases (e.g., RAS, RAF, MEK, PI3K, AKT, JAK), gene translocations resulting in activated fusion proteins (e.g., bcr-abl, EML4-ALK), and the loss of function of an inhibitor of a pathway (e.g., the PTEN phosphatase) through mutation, gene deletion, or promoter methylation. Inhibitors are shown acting on three different cells: a cancer cell, an endothelial cell, and a T cell. Antibodies (green) are shown at their extracellular protein targets. Small-molecule inhibitors (in blue) are depicted adjacent to their intracellular targets. Proteins within red ellipses provide activating signals, those in green ellipses, inhibitory signals. Star bursts (★) indicate signaling components in which mutations are common. Figure 67–4 describes mTOR signaling and its inhibition in more detail (see also Figure 35–2). Figure 67–6 describes Jak–STAT signaling in greater detail.

**Therapeutic Uses.** Antibodies targeting EGFR show a different spectrum of antitumor activity than EGFR TKIs, in part due to the additional ADCC of antibodies toward tumor cells. Cetuximab and related antibodies are used to treat patients with metastatic colon cancers and HNSCC. In colon cancer, cetuximab enhances the effectiveness of chemotherapy in patients with KRAS wild-type but not KRAS-mutant tumors (Van Cutsem et al., 2009). A combination of cetuximab with FOLFIRI (see Chapter 66) is typically used to treat patients with KRAS wild-type tumors that express EGFR. Cetuximab is also used as a single agent in patients who cannot tolerate irinotecan-based therapy and in patients with cancers that are resistant to oxaliplatin, irinotecan, and 5FU.

In HNSCC, cetuximab is used in combination with radiation or with platinum complex-based chemotherapy (e.g., cisplatin; see Chapter 66) for locally or regionally advanced HNSCC. Cetuximab is also indicated as a monotherapy for patients with metastatic or recurrent HNSCC who fail platinum-based chemotherapy.

**Adverse Effects.** Antibodies targeting EGFR have an adverse effect profile similar to that of first-generation EGFR protein tyr kinase inhibitors. Acneiform rash in the majority of patients, pruritus, nail changes, headache, and less frequently diarrhea are the most common adverse reactions. Rare but serious adverse effects include infusion reactions (~3% of patients), cardiopulmonary arrest (2%–3%), interstitial lung disease, and serum electrolyte imbalances, including hypomagnesemia. During pregnancy, cetuximab may be transmitted to the developing fetus and has the potential to cause fetal harm.

**Other EGFR Antibodies**

**Panitumumab**

Panitumumab is a recombinant, fully humanized IgG1 antibody that binds to the extracellular domain III of the EGFR and prevents ligand-dependent signaling. It is FDA approved for the treatment of EGFR-expressing mCRC in combination with chemotherapy and as monotherapy after disease progression following chemotherapy regimens containing fluoropyrimidine, oxaliplatin, and irinotecan (Saltz et al., 2006). Although panitumumab effectively inhibits EGFR signaling similarly to cetuximab, it is less effective at triggering cellular immune mechanisms that may be crucial for effective therapy of HNSCC (Trivedi et al., 2016).

**ADME: Adverse Effects.** Panitumumab exhibits nonlinear pharmacokinetic characteristics. Following intravenous administration every 2 weeks, steady-state levels are achieved by the third weekly infusion. The volume of distribution approximates the intravascular space. The half-life of cetuximab is about 5 days.

**Necitumumab**

Necitumumab is a recombinant human IgG1 monoclonal antibody that binds to the extracellular domain of the EGFR. It is approved for first-line treatment of patients with metastatic, squamous NSCLC in combination with gemcitabine and cisplatin. Necitumumab is administered intravenously every 3 weeks prior to chemotherapy. Adverse effects are similar to those of cetuximab.
Trastuzumab

**Mechanism of Action**
Trastuzumab is a humanized IgG1 monoclonal antibody that binds to the extracellular domain IV of HER2 (Figure 67–2), inhibiting hetero- and homodimerization and signal transduction. In addition, binding of trastuzumab to HER2 overexpressing cells can induce antibody-dependent, immune cell–mediated cytotoxicity. HER2 protein overexpression or gene amplification are predictive of response to HER2-targeted antibodies and a new concept in the treatment of HER2-positive breast cancers. *Trastuzumab* was the first anti-HER2 monoclonal antibody developed based on these discoveries; it was approved in the U.S. in 1998 and in Europe in 2000 for the treatment of patients with HER2-positive breast cancers. A small molecule kinase inhibitor of EGFR (HER1), *gefitinib* was approved in 1998 in the U.S. and in 2000 in Europe. A monoclonal antibody targeting EGFR, *cetuximab*, was approved in Switzerland in 2003 and in the U.S. in 2004.

**ADME**
Trastuzumab has dose-dependent pharmacokinetics with a mean $t_{1/2}$ of 5.8 days on a weekly maintenance dose with alternative dosing every 3 weeks. Steady-state levels are achieved between 16 and 32 weeks.

**Therapeutic Uses**
Trastuzumab is approved for HER2-overexpressing breast and gastric cancer. It is used in combination with cytotoxic chemotherapeutics such as taxanes as initial treatment or as a single agent following relapse of disease after cytotoxic chemotherapy (Chapter 66).

**Adverse Effects and Precautions**
Acute adverse effects after infusion of trastuzumab are typical for monoclonal antibodies and can include fever, chills, nausea, dyspnea, and rashes. The most serious toxicity of trastuzumab is heart failure. Cardiotoxicity is caused by interruption of HER2/4 heterodimer signaling in cardiomyocytes, signaling that is essential for the maintenance of contractile function. The cardiotoxic potential was predicted from gene inactivation studies (“knockouts”) in mice, which showed that mice lacking HER2, HER4, or HER ligands developed dilated cardiomyopathy and heart failure. Thus, baseline electrocardiogram and cardiac ejection fraction measurement should be obtained before initiating treatment with trastuzumab to rule out underlying heart disease. Clinical monitoring for symptoms of congestive heart failure as well as periodic determination of LVEF during and after the course of therapy is recommended. When trastuzumab is used as a single agent, fewer than 5% of patients will experience a decrease in LVEF; and about 1% will have clinical signs of congestive failure. However, left ventricular dysfunction occurs in up to 20% of patients who receive a combination of doxorubicin and trastuzumab, reflecting the added cardiotoxicity of doxorubicin. In contrast, the risk of cardiac toxicity is greatly reduced with the recommended combination of trastuzumab with taxanes.

**Pertuzumab**

**Mechanism of Action**
Pertuzumab is a humanized monoclonal antibody directed against the extracellular receptor dimerization domain II of HER2 that is distinct from domain IV targeted by trastuzumab (Figure 67–2). Pertuzumab prevents ligand-dependent heterodimerization of other HER family members with HER2 and thus inhibits ligand-induced signaling, cell growth, and survival. In addition to the inhibition of receptor heterodimerization, binding of pertuzumab to HER2 overexpressing cells can induce antibody-dependent, immune cell–mediated cytotoxicity.

**ADME**
The median half-life of pertuzumab is 18 days; after an initial loading dose, maintenance doses are administered every 3 weeks.

**Therapeutic Use**
Preclinical studies with HER2-overexpressing human tumor cells grown as xenograft tumors in mice showed that the combination of pertuzumab and trastuzumab enhanced antitumor activity. In patients with HER2-positive metastatic breast cancer, the addition of pertuzumab to trastuzumab and docetaxel increases the median overall survival by 15.7 months (Swain et al., 2015). Use of pertuzumab is approved for the treatment of patients with HER2-positive, locally advanced, inflammatory, or early stage breast cancer in combination with trastuzumab and docetaxel.

**Adverse Effects**
Cardiotoxicity is similar to that of trastuzumab, and combinations with cardiotoxic anthracyclines are not indicated (Slamon et al., 2001). On the other hand, the combination of pertuzumab and trastuzumab does not cause any increase in cardiac toxicity (Swain et al., 2015). Based on its mechanism of action, pertuzumab can cause fetal harm when administered to a pregnant woman, and this risk should be weighed against the potential benefit.

**Lapatinib**

**Mechanism of Action; ADME**
Lapatinib is an orally bioavailable, small-molecule inhibitor of the EGFR and HER2 tyrosine kinases with an IC$_{50}$ of about 10 nM. Lapatinib is metabolized by CYP3A4 with a plasma $t_{1/2}$ of 14 h. Concurrent administration of inducers and inhibitors of CYP3A4 may necessitate adjustment of the dose.

**Therapeutic Uses; Adverse Effects**
Lapatinib in combination with capecitabine is approved for the treatment of patients with metastatic HER2-positive and trastuzumab-refractory breast cancer. Lapatinib is also used in combination with the aromatase inhibitor letrozole (see Chapter 68) to treat postmenopausal women with hormone receptor–positive, metastatic breast cancer that overexpresses HER2. Frequent adverse effects include acenform rash, diarrhea, cramping, and exacerbation of gastroesophageal reflux. When lapatinib is
combined with capectabine, diarrhea is worsened. Cardiac toxicity appears less pronounced than with trastuzumab, although lapatinib should be used with caution in combination with cardiotoxic drugs: A dose-dependent prolongation of the QT interval has been reported; thus, careful monitoring of patients with heart disease is recommended.

**Neratinib**

Neratinib is an orally bioavailable, irreversible inhibitor of the HER2 and EGFR protein tyrosine kinase with IC50 values of 59 nM and 92 nM, respectively. Addition of neratinib to standard chemotheraphy that includes trastuzumab in patients with HER2-positive breast cancers has shown some efficacy. Diarrhea was the most common and frequent adverse effect, with grade 3 or 4 in over one-third of patients (Park et al., 2016).

**Inhibitors of Platelet-Derived Growth Factor Receptor (PDGFR)**

Signaling by the PDGFR plays a significant part in mesenchymal biology, including stem cell growth, and is involved in oncosogenesis through aberrant cancer cell signaling, modulation of the tumor microenvironment, and facilitation of angiogenesis and metastasis. Small-molecule protein kinase inhibitors, including imatinib (see discussion below), have been used in the treatment of patients with GISTs that carry mutations in KIT or PDGFRA (Figure 67–2). The addition of the anti-PDGFR monoclonal antibody olaratumab to doxorubicin treatment (see Chapter 66) improves overall survival of patients with STS (Judson and van der Graaf, 2016).

**Olaratumab**

**Mechanism of Action**

Olaratumab is a human IgG1 monoclonal antibody that binds to PDGFRα and blocks ligand-mediated receptor activation (Tap et al., 2016).

**Therapeutic Uses**

Olaratumab is indicated, in combination with doxorubicin, for the treatment of adult patients with STS with a histologic subtype for which an anthracycline-containing regimen is appropriate and which is not amenable to curative treatment with radiotherapy or surgery. Recent studies showed that addition of olaratumab to doxorubicin doubled median survival of patients with metastatic STS to 26 months (Judson and van der Graaf, 2016).

**Adverse Effects**

The most common (≥20%) adverse effects of treatment with olaratumab are nausea, fatigue, neutropenia, musculoskeletal pain, inflammation of the mucous membranes (mucositis), alopecia, vomiting, diarrhea, decreased appetite, abdominal pain, neuropathy, and headache. Laboratory abnormalities are lymphopenia, neutropenia, thrombocytopenia, hyperglycemia, elevated aPTT, hypokalemia, and hypophosphatemia. Other adverse effects include infusion-related reactions (low blood pressure, fever, chills, rashes) and embryo-fetal harm.

**Hedgehog Pathway Inhibitors**

The hedgehog signaling pathway was discovered by genetic studies in fruit flies: Mutations resulting in stubby and hairy Drosophila melanogaster larvae inspired the naming of the signaling pathway as “hedgehog” or Hh, which is the name of the pathway’s polypeptide ligand. Mammals have three hedgehog homologs. The hedgehog pathway controls embryonic cell differentiation in tissues of different species through distinct gradients of hedgehog signaling proteins that are key regulators during development. In adults, hedgehog signaling plays roles in stem cell regulation and tissue regeneration. BCC of the skin is one of several cancers associated with the dysregulation of this pathway.

**Vismodegib** is a first-in-class hedgehog signaling pathway inhibitor approved for the treatment of adult patients with BCC. It acts as a competitive antagonist of the SMO (“smoothens hedgehog”) receptor in the hedgehog signaling pathway. Vismodegib is indicated for patients with metastatic or relapsed BCC. The drug is also undergoing clinical trials in other cancers. Common adverse effects include GI disorders (nausea, vomiting, diarrhea, constipation), muscle spasms, fatigue, hair loss, and dysgeusia (distortion of the sense of taste). These adverse effects are mostly mild to moderate. Vismodegib can cause embryo-fetal death and severe birth defects and must not be used during pregnancy.

**Sonidegib** is a hedgehog pathway inhibitor that binds to and inhibits SMO receptor signal transduction similar to vismodegib. Sonidegib is indicated for the treatment of patients with locally advanced BCC that has recurred following surgery or radiation therapy. Adverse effects are similar to those of vismodegib.

**Inhibitors of RAF Kinase: Vemurafenib, Dabrafenib**

BRAF belongs to the RAF/mi family of serine/threonine protein kinases and plays a role in regulating signaling via MAPK (or ERK) (Figure 67–2). Mutations in RAF genes can lead to one (BRAF) or two (CRAF, BRAF) changes in amino acids, rendering these gene products oncogenic and resulting in continuous cell proliferation and the development of cancer. Activating mutations of BRAF were detected in melanoma and other tumors in 2002. A small-molecule inhibitor targeting mutated BRAF, vemurafenib, was shown to be effective in melanoma in 2010 and approved by the FDA in 2011; the first inhibitor of MEK, trametinib, was approved in 2013.
Vemurafenib
Mechanism of Action
Vemurafenib is an orally bioavailable inhibitor of mutated BRAF (V600E). The name vemurafenib® is derived from the target, that is, V600E mutated BRAF. Vemurafenib also is effective against the less common BRAF V600K mutation. Melanoma cells lacking these mutations are not inhibited by vemurafenib.

ADME
Following oral administration, the elimination half-life of vemurafenib is 57 h. Vemurafenib is a substrate of CYP3A4 and a substrate and an inhibitor of the Pgp exporter. Vemurafenib can increase concentrations of CYP1A2 substrates. Thus, concomitant use with the centrally acting \( \alpha \) adrenergic receptor agonist tizanidine, which has a narrow therapeutic window and is used as a muscle relaxant, should be avoided.

Therapeutic Uses
Vemurafenib is FDA approved for the treatment of patients with metastatic melanoma harboring activating BRAF (V600E/K) mutations. It is not indicated for the treatment of patients with melanoma carrying wild-type BRAF.

Adverse Effects
The most common adverse effects (30%-60% of patients) are cutaneous events. Arthralgia, fatigue, and nausea are also observed but at a lower frequency. cuSCCs and keratoacanthomas that may need surgical removal appear in more than 20% of patients. The median time to the first appearance of these skin lesions is 7 to 8 weeks and is caused by a paradoxical stimulation of wild-type BRAF. Increased photosensitivity reactions can be prevented with sunblock. QT prolongation has been observed, necessitating controlling for risk factors and monitoring ECG and electrolytes.

Drug Resistance
Melanoma is one of the most aggressive malignancies, with a high mutation rate that renders these tumors highly heterogeneous and thus prone to the quick development of resistance to drug treatments. After the initial response of melanoma lesions to treatment with vemurafenib, resistant cancer cell subpopulations are selected, typically in less than 6 months. Constitutively active mutant NRAS; downstream mutations in MEK; overexpression of the growth receptor PDGFR-B; activation of parallel pathways such as PI3K/Akt, mTOR, and STAT3 signaling; or stromal cell secretion of HGF can drive this drug resistance (Chapman et al., 2011). Combination treatment with a MEK inhibitor (trametinib, cobimetinib) that acts downstream of BRAF (Figure 67–2) can delay development of resistance to single-agent BRAF inhibitors (Robert et al., 2015).

Dabrafenib
Mechanism of Action
Dabrafenib is an orally bioavailable, small-molecule inhibitor of mutated forms of BRAF kinases. Dabrafenib can inhibit the proliferation of tumor cells that contain a constitutively active mutated BRAF with in vitro IC\(_{50}\) values of 0.65, 0.5, and 1.84 nM for the V600E, V600K, and V600D mutations, respectively. At about 5-fold higher concentrations, dabrafenib also inhibits wild-type BRAF and CRAF (IC\(_{50}\) values of 3.2 and 5.0 nM, respectively). Dabrafenib, in combination with trametinib (see discussion that follows), is approved for the treatment of patients with unresectable or metastatic melanoma and NSCLC with BRAF mutations. The drug is not indicated for the treatment of patients with wild-type BRAF melanoma.

ADME
The mean terminal half-life of dabrafenib is 8 h after oral administration. Dabrafenib is metabolized primarily by CYP2C8 and CYP3A4. Patients should be monitored closely for adverse reactions and for loss of efficacy if treated with drugs that induce CYP2C8 and CYP3A4 activity.

Therapeutic Uses
Dabrafenib was FDA approved as a single-agent treatment of patients with BRAF V600E mutation-positive advanced melanoma in 2013. Resistance to dabrafenib and other BRAF inhibitors occurs within about 6 months, but a combination with the MEK inhibitor trametinib can delay the development of resistance (see discussion that follows). Thus, the FDA has approved the combination of dabrafenib and trametinib for the treatment of patients with BRAF V600E/K-mutant metastatic melanoma and BRAF V600E-mutant NSCLC.

Adverse Effects and Drug Interactions
Adverse effects, in order of decreasing frequency, are hyperkeratosis, headache, pyrexia, arthralgia, papilloma, alopecia, and PPES. An increased incidence of cuSCC is expected in about 10% of patients, with a median time of 2 months to the first diagnosis. About one-third of those patients develop more than one lesion with continued administration of dabrafenib. With the dabrafenib-trametinib combination, the appearance of cuSCC is delayed to a median time of 7 months and occurs in only 3% of patients. Most common adverse reactions (≥20%) for dabrafenib in combination with trametinib are pyrexia, rash, chills, headache, arthralgia, and cough. Cardiomyopathy has also been reported.

Inhibitors of MEK: Trametinib, Cobimetinib
The MMKs or MEKs are serine-threonine kinases that act downstream of RAF. They provide additional targets for the inhibition of the RAS-RAF-MEK-ERK pathway that is frequently activated in cancer and controls cell survival, differentiation, and growth (Figure 67–2).

Trametinib
Trametinib was the first inhibitor of the MEK family to be FDA approved.

Mechanism of Action
Trametinib is an orally bioavailable, reversible, allosteric inhibitor of ATP binding to the MEK1/2 kinases. Trametinib inhibits MEK1/2 kinase activities with an IC\(_{50}\) of about 2 nM.

ADME
Bioavailability of oral trametinib is 72% and is reduced if taken with a high-calorie meal. Peak plasma concentrations are achieved 1.5 h post-dose. The drug has a relatively long half-life of 4 to 5 days. Trametinib is not a substrate of CYP enzymes and mild renal or hepatic impairment does not affect exposure to the drug significantly.

Therapeutic Uses
The FDA approved trametinib as a monotherapy for patients with mutant BRAF V600E/K melanoma due to improved survival relative to standard therapy. Trametinib in combination with the BRAF inhibitor dabrafenib is also approved for mutant V600E/K metastatic melanoma and mutant V600E metastatic NSCLC. Trametinib treatment lacks efficacy in patients who received prior treatment with BRAF inhibitors. This suggests that resistance to BRAF and MEK inhibitors involves similar mechanisms (Kim et al., 2013).

Adverse Effects
The most frequent adverse effects are cutaneous rash, acniform dermatitis, and diarrhea. Fatigue, nausea, and lymphedema also occur. Serious grade 3–4 skin toxicity is found in 6% of patients. Other serious adverse effects are cardiomyopathy, hypertension, hemorrhage, interstitial lung disease, and ocular toxic effects. In contrast to the BRAF inhibitors, trametinib does not cause cuSCC. Because trametinib can cause fetal harm when administered to a pregnant woman, this risk must be weighed against the potential benefit.

Drug Resistance
Activation of alternative signaling pathways that include PI3K/Akt, mTOR, and STAT3 signaling can bypass MEK inhibition and result in drug-resistant tumors. Also, mutations in the allosteric binding pocket and activation loop of MEK1 can inhibit the binding of the inhibitor.
and cause resistance to trametinib. Resistance to single-agent trametinib occurs within 6 to 7 months of the initiation of treatment at a rate approaching 50%. As a strategy to overcome resistance, trametinib has been combined with the BRAF inhibitor dabrafenib for the treatment of patients with BRAF V600E/K-mutant metastatic melanoma (Flaherty et al., 2012). This combination has been approved by the FDA.

Cobimetinib

**Mechanism of Action; ADME**

Cobimetinib is an orally bioavailable, reversible inhibitor of MEK1/2 protein kinase activity with an IC_{50} of about 4nM. Its elimination half-life ranges from 1 to 3 days. Cobimetinib is a substrate for CYP3A, and concomitant treatment with inducers or inhibitors of CYP3A will reduce or increase the systemic exposure of patients.

**Therapeutic Uses**

A combination of cobimetinib and vemurafenib is FDA approved for the treatment of patients with unresectable or metastatic melanoma with a BRAF V600E/K mutation.

**Adverse Effects**

The most common adverse effects are diarrhea, photosensitivity reaction, nausea, pyrexia, and vomiting. Major hemorrhagic events can occur with cobimetinib; patients should be monitored for signs and symptoms of bleeding. The drug also increases the risk of cardiomyopathy; the safety in patients with decreased LVEF has not been established.

**Other MEK Inhibitors**

Under development are binimetinib, a MEK inhibitor being studied in patients with NRAS-mutant melanoma, and encorafenib, a BRAF inhibitor being used in combination with binimetinib for patients with BRAF-mutant melanoma.

Inhibitors of Jak1 and Jak2

Janus associated kinases (Jaks) mediate the signaling of cytokines and growth factors in hematopoiesis and immune function (see, for instance, Figure 35–2). Intracellular Jak signaling recruits STATs to cytokine membrane receptors (Figure 67–2). After STAT activation and subsequent localization to the nucleus, STATs modulate gene expression. Jak signaling is dysregulated in myelofibrosis and polycythemia vera, which prompted the development of Jak inhibitors. Ruxolitinib is the first drug in this class.

**Ruxolitinib**

**Mechanism of Action; ADME**

Ruxolitinib is an orally bioavailable (95%) analogue of ATP that inhibits the protein kinase activities of Jak1 and Jak2 (IC_{50} value of 3 nM) and exhibits more than 100-fold selectivity for Jak1/2 over Jak3. The half-life of ruxolitinib is about 3 h; its metabolism is mainly via hepatic CYP3A4, with products excreted largely in the urine. In patients with renal or hepatic impairment, a dose reduction is recommended.

**Therapeutic Uses**

Ruxolitinib is indicated for the treatment of patients with polycythemia vera who have had an inadequate response to hydroxyurea and for the treatment of myelofibrosis.

**Adverse Effects and Drug Interactions**

The most common adverse reactions, thrombocytopenia and anemia, should be met with a dose reduction or discontinuation of treatment. Infections should be resolved before treatment with ruxolitinib. In a few patients, BCC or squamous cell skin carcinoma may occur, warranting periodic skin examinations during treatment. Strong CYP3A4 inhibitors (e.g., ketoconazole, fluconazole) increase exposure to ruxolitinib and prolong its half-life to 6 h. Due to the adverse hematopoietic effects, postpartum patients should discontinue nursing during drug treatment.

**Cyclin-Dependent Kinase (CDK) 4/6 Inhibitors**

The CDKs are a family of over 20 serine/threonine protein kinases that modulate intracellular signaling during cell cycle progression (Figure 67–2). Given their pivotal role in cellular proliferation, CDKs are prime targets for development of inhibitors. However, different tissue selectivity and distinct cell cycle–specific activity periods of different CDKs provide a challenge.

CDK4/6 are attractive targets because they control cell cycle progression from the G_{1}/G_{0} to S phase. Interaction of cyclin D with CDK4/6 enhances phosphorylation of the Rb tumor suppressor protein, inactivating Rb and permitting the transcription of factors that control transition into the S phase. Inhibition of CDK4/6 will inhibit the phosphorylation and inactivation of Rb and cause a G_{1} arrest in susceptible cells that utilize this pathway, thereby providing the rationale for the use of inhibitors of CDK4/6 (Figure 67–3). This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6, such as p16^{INK4A}, a tumor suppressor named for its molecular mass (it is a small protein of 16 kDa) and its capacity to inhibit CDK4. The class of CDK inhibitory drugs is identified by the syllable cibib and includes palbociclib, discussed next.

**Palbociclib**

**Mechanism of Action**

Palbociclib is an orally bioavailable, small-molecule inhibitor of CDK4 and CDK6, with IC_{50} values of 11 and 16 nM, respectively, and without inhibitory activity against CDK1, 2, or 5.

---

**Figure 67–3** CDK4 inhibitors: retinoblastoma protein, cyclin-dependent protein kinases, and the regulation of cell cycle progression. In quiescent and differentiated cells (in G_{0} or in cells arrested in G_{1}), the Rb protein is active and interacts with a heterodimer of the transcription factor E2F and its dimerization partner DP1, repressing transcription of promoters regulated by E2F. As a cell begins a cycle of division, cyclins activate CDKs that phosphorylate Rb, disrupting the Rb-E2F/DP complexes and permitting accumulation of active E2F complexes that drive transcription. This cell cycle checkpoint is frequently compromised in cancers due to cyclin D amplification, loss of Rb function, or loss of negative regulators of CDK4/6. Hyperphosphorylation of Rb can occur via mutations in Rb or expression of viral oncoproteins targeting Rb, placing the cell in a state of extensive proliferation, with reduced capacity to exit the cell cycle. Inhibition of CDK4/6 can cause G_{1} arrest in susceptible cells (Dyson, 2016). CDK inhibitors (in red lettering) are identified by the syllable ciclib.
ADME
The mean plasma elimination half-life is 29 h. Palbociclib is a substrate and an inhibitor of CYP3A; thus, doses of palbociclib or of substrates of CYP3A4 may need to be reduced when they are given concurrently, with special attention to concomitantly administered agents with narrow therapeutic indices (see the Adverse Effects and Drug Interactions section). The sulfotransferase SULT2A1 also participates in palbociclib metabolism.

Therapeutic Uses
Palbociclib is the first CDK inhibitor approved by the FDA for the treatment of advanced or metastatic breast cancer that is ER positive and HER2 negative. Palbociclib is used in combination with letrozole, an aromatase inhibitor, as initial endocrine-based therapy in postmenopausal women with or without the antiestrogen fulvestrant in women with breast disease progression after endocrine-based therapy. Letrozole and fulvestrant are described in Chapter 68. The inclusion of palbociclib with different endocrine-based treatments almost doubles the progression-free survival of patients (Cristofanilli et al., 2016; Finn et al., 2016).

Adverse Effects and Drug Interactions
The most common adverse effects of palbociclib are neutropenia, leukopenia, infections, stomatitis, fatigue, nausea, anemia, headache, diarrhea, and thrombocytopenia. The most common grades 3 and 4 adverse effects are neutropenia (>60%), leukopenia (>25%), and anemia (>5%). Patients should avoid breastfeeding while taking palbociclib. Letrozole and fulvestrant do not alter the pharmacokinetics of palbociclib.

Patients should avoid concomitant use of strong CYP3A inhibitors (e.g., clarithromycin, itraconazole, ketoconazole, lopinavir/ritonavir, nefazodone, nelfinavir, posaconazole, ritonavir, saquinavir, telaprevir, telithromycin, and voriconazole). Coadministration of a strong CYP3A inhibitor (e.g., itraconazole) can markedly increase exposure to palbociclib (by 87% in healthy subjects). Patients should avoid grapefruit or grapefruit juice. If palbociclib coadministration with a strong CYP3A inhibitor cannot be avoided, reduce the dose of palbociclib.

Coadministration of a strong CYP3A inducer will decrease exposure to palbociclib. Thus, avoid concomitant use of phenytoin, rifampin, carbamazepine, enzalutamide, and St. John's Wort.

Palbociclib may increase exposure to coadministered CYP3A substrates with narrow therapeutic indices (e.g., midazolam, alfentanil, cyclosporine, dihydroergotamine, ergotamine, everolimus, fentanyl, pimozide, quinidine, sirolimus, and tacrolimus), requiring reduction of palbociclib dose.

Other Drugs That Target CDK4/6
Abemaciclib and ribociclib are CDK4/6 inhibitors with inhibitory profiles similar to that of palbociclib. These inhibitors are currently undergoing clinical trials in patients with breast cancer as well as a variety of other cancers. Ribociclib is FDA-approved for treating breast cancer. The major efficacy and adverse effects of these inhibitors appear to overlap. However, differences in the selectivity for the targeted kinases appear to result in different adverse effect profiles and possibly future uses of these inhibitors (O'Leary et al., 2016).

Bruton Tyrosine Kinase (BTK) Inhibitor
The BTK protein tyrosine kinase plays important roles in the function of B cells. The PH domain of BTK binds PIP3. BTK-PIP3 phosphorylates PLC, which hydrolyzes phosphatidylinositol, thereby activating the IP3-Ca2+ PKC pathway in B cells.

Ibrutinib
Mechanism of Action
Ibrutinib is an orally bioavailable, small-molecule inhibitor that inactivates BTK through covalent binding to cys385 near the ATP-binding domain.

ADME
Administration with food (vs. an empty stomach) roughly doubles absorption. The elimination half-life of ibrutinib is 4 to 6 h. It is a substrate of CYP3A; CYP2D6 participates to a minor degree. Metabolites are excreted mainly via the feces; renal excretion is minor. Hepatic impairment is likely to increase ibrutinib exposure. Ibrutinib is not a substrate for Pgp.

Therapeutic Uses
Ibrutinib inhibits malignant B-cell proliferation and is indicated for the treatment of patients with MCL who have received at least one prior therapy, CLL, SLL, and WM.

Adverse Effects and Drug Interactions
The most common adverse effect (≥20%) in patients with B-cell malignancies are neutropenia, pyrexia, thrombocytopenia, hemorrhage, anemia, diarrhea, nausea, musculoskeletal pain, rash, and fatigue. The onset of hypertension has been observed within less than a month and up to 2 years after the start of ibrutinib treatment. Thus, blood pressure should be monitored and antihypertensive treatment initiated or modified. Atrial fibrillations are observed in up to 7% of patients; this requires monitoring and treatment. Second primary malignancies occur in up to 16% of patients, most of them nonmelanoma skin cancers.

Strong (e.g., azole antifungals) and moderate (e.g., diltiazem, erythromycin) CYP inhibitors will increase ibrutinib's AUC; thus, dose reduction is recommended when using CYP3A inhibitors concomitantly. The reverse is true for strong and moderate CYP inducers (e.g., rifampin, efavirenz), which will decrease ibrutinib exposure.

Ibrutinib is classified pregnancy category D (see Appendix I) and may cause fetal harm. Pregnant patients and those at risk for pregnancy should be apprised of the drug's hazardous potential.

Acalabrutinib is a second-generation, orally bioavailable, irreversible BTK inhibitor that shows higher selectivity for BTK versus other kinases (e.g., EGFR, ITK) than ibrutinib. Acalabrutinib appears to have less-frequent off-target toxicities. Acalabrutinib received orphan drug designation for the treatment of CLL in the U.S. and for CLL, SLL, MCL, or WM in Europe.

Inhibitors of the BCR-ABL Kinase
A single molecular event, the Philadelphia chromosome translocation t(9;22), leads to expression of ABL and BCR. This fusion generates a constitutively active protein kinase, BCR-ABL, resulting in continuous and uncontrollable cell division. BCR-ABL drives the malignant phenotype of CML (Figure 67–2).

HISTORY BCR-ABL Kinase Inhibitors
Imatinib mesylate, originally named “sti 571” (signal transduction inhibitor 571), was the first protein kinase inhibitor designed to target a driver mutation in a cancer and to receive FDA approval. It was approved in 2001 under the name Gleevec and is now designated as an essential drug by the World Health Organization (WHO). Imatinib targets the BCR-ABL tyrosine kinase fusion protein that drives CML. Imatinib-resistant ABL mutations were uncovered in 2002 and led to the development of next-generation inhibitors dasatinib and nilotinib, which overcome the resistance.

Imatinib and the second-generation inhibitors dasatinib and nilotinib induce clinical and molecular remissions in more than 90% of patients with CML in the chronic phase of disease. Due to its inhibition of other kinases, imatinib is also effective in some other tumors, including GISTs (driven by a c-KIT mutation), hyperesinophilia syndrome, and dermatofibrosarcoma protuberans (all driven by activating mutations in the PDGFR; see Figure 67–2).

Imatinib, Dasatinib, and Nilotinib
Mechanisms of Action
These are orally bioavailable, small-molecule kinase inhibitors. Imatinib was identified through high-throughput screening against the BCR-ABL kinase. Dasatinib, a second-generation BCR-ABL inhibitor, also inhibits
Mechanisms of Resistance

Resistance to these TKIs arises from point mutations in three separate segments of the kinase domain. The contact points between imatinib and the enzyme become sites of mutations in drug-resistant leukemic cells; these mutations prevent tight binding of the drug and lock the enzyme in its open configuration, in which it has access to substrate and is enzymatically active. Imatinib retains inhibitory activity in the presence of most point mutations that confer resistance to imatinib. Other mutations affect the phosphate-binding region and the “activation loop” of the domain with varying degrees of associated resistance. Some mutations, such as those at amino acids 351 and 355, confer low levels of resistance to imatinib, possibly explaining the clinical response of some resistant tumors to dose escalation of imatinib.

Molecular studies have detected cells with resistance-mediating kinase mutations prior to initiation of therapy, particularly in patients with Ph+ ALL or CML in blast crisis. This finding indicates that drug-resistant cells arise through spontaneous mutation and expand under the selective pressure of drug exposure. Mechanisms other than BCR-ABL kinase mutations play a minor role in resistance to imatinib. Amplification of the wild-type kinase gene, leading to overexpression of the enzyme, has been identified in tumor samples from patients resistant to treatment. The MDR gene confers resistance experimentally but has not been implicated in clinical resistance. Ph+ clones lacking the BCR-ABL translocation and displaying the karyotype of myelodysplastic cells may emerge in patients receiving imatinib for CML; these may progress to MDS and AML. Their origin is unclear.

A comparison amongst secondary mutations in the EGFR, ABL, and KIT kinases following treatment with BCR-ABL kinase inhibitors shows striking differences: The T790M gatekeeper mutation in the EGFR (Figure 67–1) accounts for about 90% of secondary mutations. In contrast, secondary resistance mutations in ABL or KIT after treatment of CML or GIST with imatinib are found across the kinase domain and rarely at the analogous gatekeeper residue in ABL (T170) or in KIT (T170).

ADME

Imatinib is well absorbed after oral administration and reaches maximal plasma concentrations within 2–4 h. The elimination \( t_{1/2} \) of imatinib and its major active metabolite, the N-desmethyl derivative, are about 18 and 40 h, respectively. Food does not change the pharmacokinetic profile. Doses of more than 300 mg/d achieve trough levels of 1 μM, which correspond to in vitro levels required to kill BCR-ABL–expressing cells. In the treatment of GISTs, higher doses may improve response rates. CYP3A4 is the major metabolizer of imatinib; thus, drugs that induce or interact with CYP3A4 can alter the pharmacokinetics of imatinib. Coadministration of imatinib and rifampin, an inducer of CYP3A4, lowers the plasma imatinib AUC by 70%. Imatinib, as a competitive CYP3A4 substrate, inhibits the metabolism of simvastatin and increases its plasma AUC by 3.5-fold.

Dasatinib. Oral dasatinib is well absorbed; its bioavailability is significantly reduced at neutral gastric pH (i.e., after antacids and H₂ blockers) but is unaffected by food. The plasma \( t_{1/2} \) of dasatinib is 3–5 h. Dasatinib exhibits dose-proportional increases in AUC, and its clearance is constant over the dose range of 15–240 mg/d. Dasatinib is metabolized primarily by CYP3A4, with minor contributions by FMO3 and UGT. The major metabolite is equipotent to the parent drug but represents only 5% of the AUC. Plasma concentrations of dasatinib are affected by inducers and inhibitors of CYP3A4 in a similar fashion to imatinib.

Nilotinib. Approximately 30% of an oral dose of nilotinib is absorbed after administration, with peak concentrations in plasma 3 h after dosing. Unlike the other BCR-ABL inhibitors, nilotinib's bioavailability increases significantly in the presence of food. The drug has a plasma \( t_{1/2} \) about 17 h, and plasma concentrations reach a steady state only after 8 days of daily dosing. Nilotinib is metabolized by CYP3A4, with predictable alteration by inducers, inhibitors, and competitors of CYP3A4. Nilotinib is a substrate and an inhibitor of Pgp.

Therapeutic Uses

These protein TKIs have efficacy in diseases in which ABL, KIT, or PDGFR have dominant roles in driving tumor growth, reflecting the presence of a mutation that results in constitutive activation of the kinase. Imatinib shows therapeutic benefits in patients with chronic-phase CML (BCR-ABL) or GIST and a subset of patients with mucosal or acral lentiginous melanoma (KIT mutation positive), chronic myelomonocytic leukemia (EV766-PDGFR translocation), hypereosinophilia syndrome (FIP1L1-PDGF), and dermatofibrosarcoma protuberans (constitutive production of the ligand for PDGFR). It is the agent of choice for patients with metastatic GIST and is used as adjuvant therapy of c-KIT–positive GIST. Dasatinib is approved for patients with newly diagnosed CML with resistance or intolerance of imatinib in both chronic and advanced phases of disease and for use combined with cytotoxic chemotherapy in patients with Ph+ ALL who are resistant or intolerant to prior therapies.

Adverse Effects

Imatinib, dasatinib, and nilotinib cause GI symptoms (diarrhea, nausea, and vomiting) that are usually readily controlled. All three drugs promote fluid retention, edema, and periorbital swelling. Myelosuppression occurs infrequently but may require transfusion support and dose reduction or discontinuation of the drug. These drugs can be associated with hepatoxicity. Dasatinib may cause pleural effusions and pulmonary hypertension in a small subset of patients. Nilotinib and dasatinib may prolong the QT interval; nilotinib has been associated with cardiac and vascular events, including ischemia. Most nonhematological adverse reactions are self-limited and respond to dose adjustments. After the adverse reactions have resolved, the drug may be reinitiated and titrated back to effective doses.

Bosutinib

Bosutinib is another second-generation, orally bioavailable BCR-ABL kinase inhibitor (IC₅₀ = 1.2 nM). Bosutinib also inhibits activity of Src (IC₅₀ = 1 nM) and other members of the Src family. It is FDA approved for the treatment of patients with chronic, accelerated, or blast-phase Ph⁺ CML with resistance or intolerance to prior therapy. The most common adverse reactions (incidence greater than 20%) are diarrhea, nausea, thrombocytopenia, vomiting, abdominal pain, rash, anemia, pyrexia, and fatigue.

Ponatinib

Ponatinib is a third-generation BCR-ABL kinase inhibitor. Imatinib (first generation) lacks efficacy for the more advanced disease phases, and cells with mutations in the BCR-ABL tyrosine kinase domain are resistant. Second-generation inhibitors (nilotinib, dasatinib, bosutinib) were developed to address these weaknesses, although they do not inhibit the T315I mutant of BCR-ABL that is found in 15%–20% of patients with CML.

Mechanism of Action

Ponatinib is a third-generation, orally bioavailable kinase inhibitor that is active against the T315I mutant BCR-ABL and also is effective toward all other known BCR-ABL1 kinase mutants. IC₅₀ values (nM) for different kinases are as follows: ABL, 0.37; PDGFR, 1.1; VEGFR2, 1.5; FGFR1, 2.2; and Src, 5.4.

ADME

Peak ponatinib concentrations are observed within 6 h and are unaffected by food or fasting. Drug solubility is pH dependent, with higher pH resulting in decreased solubility. Accordingly, drugs that affect gastric pH (such
as H₂ antagonists, antacids, and PPIs) may significantly alter ponatinib bioavailability. Ponatinib is highly (99%) bound to plasma proteins and is a weak substrate for Pgp and ABCG2 transporters. Metabolism is primarily via CYP3A4 and to lesser extents by CYPs 2C8, 2D6, and 3A511; esterases; and amidases. Coadministration of CYP3A inhibitors significantly increases ponatinib concentrations. The t₁/₂ of ponatinib is about 24 h. Unmetabolized ponatinib is primarily excreted in the feces (87%), with a small portion (5%) in the urine.

**Therapeutic Uses**
Ponatinib is approved for resistant CML and Ph⁺ ALL. Clinical cytogenetics measurements are a key tool for monitoring the response to therapy, reported as the percentage of Ph⁺ karyotypes in 20 bone marrow metaphases (major cytogenetic response; MCyR). Ponatinib produces an overall 54% MCyR in patients with early-phase CML and a 70% MCyR in patients with early-phase CML with the T315I mutation. Because of ponatinib’s potency and efficacy against all known BCR-ABL single mutants, trials are under way that may advance this therapy to a first-line treatment.

**Adverse Effects**
Arterial thrombosis and hepatotoxicity are major adverse effects; thus, appropriate precautions, dose reduction, monitoring, or discontinuation are recommended following arterial thrombotic or hepatotoxic events. Dose-limiting toxicities include elevated lipase or amylase levels and pancreatitis.

---

**Inhibitors of Anaplastic Lymphoma Kinase (ALK)**
ALK is a membrane monospan with an extracellular domain and an intracellular protein tyrosine kinase domain (Figure 67–2). The importance of this protein kinase in human cancers is the capacity of the ALK gene to form fusion genes that become oncogenic drivers. A 2.5 megadalton translocation yields an oncogenic fusion gene in which a 3’ portion of ALK (chromosome 2) contributes coding for the catalytic domain and is joined to a 5’ region of the NPM gene. The extracellular and transmembrane sequences of ALK are absent in the ALK-NPM fusion gene, which is the oncogenic driver of malignant progression in anaplastic large cell lymphoma (ALCL). A similar translocation of the ALK kinase and fusion with EML4 creates the oncogenic driver in a subset of NSCLC (Martelli et al., 2010), as shown in Figure 67–2. ALK also fuses with numerous additional 5’ partners (Roskoski, 2017). Alectinib, ceritinib, and crizotinib are small-molecule inhibitors of ALK kinase that are used in the treatment of ALK translocation-positive cancers.

**Crizotinib**

**Mechanism of Action**
Crizotinib is an orally bioavailable inhibitor of receptor tyrosine kinases that include HGFRCMET, ALK, and ROS1. IC₅₀ values are 11 nM and 24 nM for HGFRCMet and ALK, respectively.

**ADME**
Crizotinib is predominantly metabolized by CYP3A4/5 and shows a terminal half-life of 42 h. The typical dose of 250 mg twice daily is reduced to once daily in patients with severe renal impairment and a creatinine clearance below 30 mL/min.

**Therapeutic Uses**
Crizotinib is approved for the treatment of patients with locally advanced or metastatic NSCLC harboring ALK or ROS1 gene rearrangements (Figure 67–2) (Thomas et al., 2015). The ROS1 gene product is a receptor tyrosine kinase that is structurally similar to ALK. ROS1 also participates in gene translocations and the formation of oncogenic fusion genes that have a 1% incidence in lung cancers.

**Adverse Effects**
The most common adverse reactions are GI toxicity including nausea, diarrhea, and vomiting as well as hepatic, respiratory, and ocular toxicity and neuropathy. Also observed are QT prolongation and bradycardia.

**Alectinib**

**Mechanism of Action**
Alectinib is an orally bioavailable inhibitor of ALK kinase activity with an IC₅₀ of 1.9 nM. Alectinib shows a higher selectivity for ALK than crizotinib and is active against mutant forms of ALK that are found in tumors resistant to crizotinib.

**ADME**
Alectinib has an elimination half-life of 33 h and is metabolized by CYP3A4. Coadministration of alectinib with CYP3A inhibitors or inducers will alter plasma concentrations.

**Therapeutic Uses**
Alectinib is approved for the treatment of patients with advanced or recurrent NSCLC harboring the ALK fusion gene (ALK⁺). Patients with ALK⁺ NSCLC who have progressed on treatment with crizotinib or are intolerant to crizotinib also qualify.

**Ceritinib**
Ceritinib is an orally bioavailable ALK inhibitor approved for the treatment of ALK⁺ metastatic NSCLC that is unresponsive to crizotinib. Common adverse effects are GI toxicity and hepatotoxicity. Bradycardia and prolonged QT intervals also occur.

---

**Inhibitors of the PI3K/Akt/mTOR Pathway**

**Background**
Activation of PI3K and the consequent activation of signaling events through protein kinase B (Akt) and the mechanistic or mTOR pathway are important in cell growth and survival and in regulation of cell metabolism (Figures 67–2 and 67–5). Excessive signaling through the PI3K pathway is a frequent aberration in many human cancers; thus, this pathway is an attractive target in cancer therapy. There are three classes of PI3Ks: The class 1 PI3K enzymes are the most important in cancer. These isoforms are activated by receptor protein tyrosine kinases and GPCRs. The PI3K enzymes are heterodimers of a p85 regulatory subunit and a p110 catalytic subunit. The p110 subunit exists in four identified isoforms: α, β, γ, and δ. The α and β isoforms are ubiquitously expressed, whereas the γ and δ isoforms are predominantly expressed in cells of hematopoietic origin. The different catalytic subunits have distinct roles in normal and malignant B-cell function. PI3Ka, containing the 110α, catalytic subunit, is the most frequently mutated PI3K in human cancer (Fruman and Rommel, 2014). In B-cell malignancies, the PI3Kδ isoform is frequently activated. A recently approved PI3Kδ inhibitor, idelalisib, is described in the next section. Currently, the mTORC1 inhibitors sirolimus (rapamycin), everolimus, and temsirolimus are approved for clinical use in different cancers and are described in the material that follows. Ongoing clinical trials are evaluating the safety and efficacy of pan-PI3K inhibitors, inhibitors of the PI3Ka isoform, as well as inhibitors of AKT, PI3Ka/mTOR, and TORC1/TORC2.

**PI3Kδ Inhibitor: Idelalisib**
The PI3Kδ isoform is constitutively activated in many B-cell malignancies, and inhibition of this pathway can promote apoptosis in these cancer cells.

**Mechanism of Action**
Idelalisib is an orally bioavailable inhibitor of the PI3Kδ isoform with an IC₅₀ of about 8 nM. It is 40- to 300-fold more selective for the PI3Kδ isoform than for the other isoforms.

**ADME**
Food does not affect absorption of idelalisib. The drug is metabolized by aldehyde oxidase, CYP3A, and UGT1A4, yielding an elimination half-life.
of 8.2 h. Idelalisib inhibits CYP3A and is a substrate of Pgp and of the efflux transporter BCRP/ABCG2 in vitro. Idelalisib increases plasma levels of midazolam (a CYP3A substrate) but does not affect plasma levels of digoxin (a Pgp substrate) or rosuvastatin (an OATP1B1/B3 substrate). Patients receiving strong CYP inhibitors may be at increased risk for idelalisib toxicity. Hepatic impairment increases systemic exposure, putting patients at risk for toxicity.

**Clinical Use**

Idelalisib is approved for the treatment of relapsed or refractory B-cell malignancies in patients who have received at least two prior systemic therapies. This includes CLL in combination with rituximab, FL, and SLL. Idelalisib is not indicated and is not recommended for first-line treatment.

**Adverse Effects**

Idelalisib may cause serious and sometimes-fatal adverse effects, including liver toxicity, diarrhea, colitis, pneumonitis, intestinal perforations, and skin toxicity. Patients taking idelalisib should avoid other hepatotoxic drugs. Other common side effects include fever, chills, cough, pneumonia, fatigue, nausea, abdominal pain, rash, hyperglycemia, and elevated levels of triglycerides and liver enzymes. Idelalisib may cause embryo-fetal toxicity. Breastfeeding during therapy is contraindicated because of the potential for adverse reactions in nursing infants.

**mTOR Inhibitors: Rapamycin Analogues**

Rapamycin (sirolimus) is a product from a strain of Streptomyces found on the Rapa Nui Easter Island. It inhibits a serine/threonine protein kinase in mammalian cells named mTOR. The PI3K/PKB(Akt)/mTOR pathway responds to a variety of signals from growth factors. The activation of the PI3K pathway is opposed by the phosphatase activity of the tumor suppressor, PTEN (Figure 67–2). Activating mutations and amplification of genes in the receptor-PI3K pathway, and loss of function alterations in PTEN, occur frequently in cancer cells, with the result that PI3K signaling is exaggerated, and cells exhibit enhanced survival. Rapamycin (sirolimus) and its congeners, the so-called rapalogs temsirolimus and everolimus, are first-line drugs in posttransplant immunosuppression (see Figure 35–2) and are used in coronary artery stents to prevent fibrotic growth. Rapalogs have been approved for the treatment of patients with renal cancer; NETs of the pancreas; NETs of GI tract or lung origin; anti–hormone refractory; hormone receptor–positive breast cancer; and for patients with TSC-related tumors.

**Mechanism of Action**

The rapamycins inhibit an enzyme complex, mTORC1, which occupies a downstream position in the PI3K pathway (Figure 67–4). mTOR forms the mTORC1 complex with a member of the FK506-binding protein family, FKBP12. The antitumor actions of the rapamycins result from their binding to FKBP12 and preventing activation of mTOR, as detailed in Figure 67–4 and its legend.

**ADME**

For renal cell cancer, temsirolimus is given in weekly intravenous doses of 25 mg: temsirolimus is metabolized by CYP3A4; the parent drug has a plasma t½ of 30 h, but its primary active metabolite, sirolimus (rapamycin), has a t½ of 53 h. Because sirolimus has equivalent activity as an inhibitor of mTORC1 and has a greater AUC, sirolimus is likely the more important contributor to antitumor action in patients. The concomitant use of strong CYP3A4 inhibitors or inducers should thus be avoided. Grapefruit juice may also increase plasma concentrations of the active metabolite sirolimus and should be avoided.

Everolimus is administered orally in doses of 10 mg/d and is metabolized by CYP3A4. Everolimus has a plasma t½ of 30 h; on a weekly schedule at doses of 20 mg, it maintains inhibition of mTORC1 for 7 days in white blood cells. Both drugs are susceptible to interactions with other agents that affect CYP3A4 activity. For everolimus, the dose should be reduced for patients with moderate hepatic impairment; guidelines for dose reduction of temsirolimus in such patients have not been established. The drugs’ pharmacokinetics do not depend on renal function, and hemodialysis does not hasten temsirolimus clearance.

**Therapeutic Uses**

Temsirolimus and everolimus are approved for treatment of patients with advanced renal cancer. Temsirolimus prolongs survival and delays disease progression in patients with advanced and poor- or intermediate-risk renal cancer, as compared to standard IFN-a treatment. Everolimus, as compared to placebo, prolongs survival in patients who had failed initial treatment with antiangiogenic drugs. mTOR inhibitors also have antitumor activity against MCLs. Everolimus is approved for the treatment of postmenopausal women with advanced hormone receptor–positive, HER2-negative breast cancer in combination with exemestane after failure of treatment with letrozole or anastrozole. Other indications are PNET and progressive, well-differentiated, nonfunctional NETs of GI or lung origin as well as TSC-related tumors.

**Adverse Effects; Resistance**

The rapamycin analogues cause similar patterns of adverse effects: a mild maculopapular rash, mucositis, anemia, and fatigue (30%–50%). A few patients will develop leukopenia or thrombocytopenia, effects that are reversed if therapy is discontinued. Less common side effects include hyperglycemia, hypertriglyceridemia, and, rarely, pulmonary infiltrates and interstitial lung disease. Pulmonary infiltrates emerge in 8% of patients receiving everolimus and in a smaller percentage of those treated with temsirolimus. If symptoms such as cough or shortness of breath develop or radiologic changes progress, the drug should be discontinued. Prednisone may hasten the resolution of radiologic changes and symptoms.

Resistance to mTOR inhibitors is incompletely understood but may arise through the action of a second mTOR complex, mTORC2, which is unaffected by rapamycins and which can upregulate Akt activity (Figure 67–4).

**Multikinase Inhibitors**

Selectivity of small-molecule protein kinase inhibitors for their targets is dependent on the similarity of the targeted site with sites in other kinases and the chemical composition of the inhibitor. Most inhibitors interact with the ATP-binding site of their target that is relatively conserved within a kinase family; thus, such inhibitors have only relative specificity and will cross-react at higher concentrations with closely related kinases. Nonetheless, inhibition of distantly related kinases is possible. The selectivity of inhibitors for a range of targets in the kinome is determined experimentally using assays with recombinant kinase proteins and in vivo using intact cells that express the kinases (Elkins et al., 2015). Inhibitors that target multiple kinase families within the clinically used dose range can be therapeutically efficacious and are discussed in the material that follows. In using drugs directed toward protein kinases, remember that the specificity of these agents is not absolute and that the inhibited kinases often serve important “normal” functions in the cell in addition to the pathologic functions being targeted.

**Cabozantinib**

**Mechanism of Action**

Cabozantinib is an orally bioavailable, small-molecule protein kinase inhibitor of several tyrosine kinases; as ranked by the IC₅₀ values (in nM) from in vitro assays, these protein kinases are VEGFR2, 0.035; MET, 1.3; RET, 4; KIT, 4.6; VEGFR, 3.6; AXL, 7; FLT3, 11.3; VEGFR1, 12; and TIE2, 14.3. These receptor tyrosine kinases control normal cellular function and pathologic processes that include maintenance of the tumor microenvironment, tumor angiogenesis, and metastatic spread.

**ADME**

The elimination half-life of cabozantinib is about 99 h. Cabozantinib is a substrate of CYP3A4; thus, the dose of cabozantinib should be reduced in patients with mild-to-moderate hepatic impairment as well as for concurrent administration of CYP3A4 inhibitors. Conversely, strong inducers of CYP3A4 will reduce exposure to the drug and necessitate increased dosage of cabozantinib unless the CYP inducers can be avoided.
**Figure 67–4** Caveat mTOR: effect of rapamycin on growth factor signaling. The PI3K-mTOR pathway responds to extracellular signals, the metabolic and nutrient status, and the energy charge of the cell, transmitting signals downstream that drive maintenance and proliferation (Hall, 2016). mTOR activity appears to contribute to resistance to many targeted cancer therapies (Guri and Hall, 2016), and dysregulation of the pathway is implicated in diabetes, cancer, and other pathologies (Dibble and Cantley, 2015). In this simplified version of the PI3K-mTOR pathway, the green shapes show the action pathway from membrane receptor to the mTOR multiprotein complex, mTORC1. Substrates of the mTOR ser/thr protein kinase activity and integrated responses are shown in blue across the bottom of the figure. Red T bars represent inhibitory influence. Signaling through the pathway is initiated by agonist activation of membrane receptors such as IGF1R and stimulation of their tyr kinase activities, leading to activation of PI3K, which phosphorylates the inositol ring of the PIP2 in the membrane to produce PIP3. PIP3 recruits to the membrane several proteins containing PH domains, including PKD1 and Akt. Akt, also known as PKB, phosphorylates TSC-2 (a subunit of TSC) at multiple sites. TSC is a GAP for Rheb. Phosphorylation of TSC inhibits its GAP activity, thereby reducing the GTPase activity of Rheb and increasing the fraction of Rheb in the GTP-liganded state. Rheb, in its GTP-ligated configuration, activates mTORC1. TSC phosphorylation and PIP3 phosphorylation can be reversed by the phosphatase PTEN. mTORC1 phosphorylates substrates that mediate downstream effects; amongst them are the following:

- **HIF-1**, leading to increased angiogenesis. HIF-1 is overexpressed in many cancers.
- **S6K1**, enhancing protein synthesis. Dephospho S6K1 exists in a complex with eIF3; phosphorylation by mTOR dissociates the complex, freeing S6K1 to phosphorylate its targets that promote translation.
- **4EBP** (eukaryotic initiation factor 4e binding protein), thereby enhancing translation. 4EBP is a repressor of mRNA translation via its inhibitory interaction with eukaryotic initiation factor 4E (eIF4E). The phosphorylation of 4EBP by mTOR reduces the capacity of 4EBP to inhibit eIF4E and slow translation.
- **ULK1** (unc-51 like autophagy activating kinase 1), whose phosphorylation reduces autophagic activity. mTOR activity prevents ULK1 activation by disrupting its interaction with AMP-activated protein kinase (AMPK), a key promoter of autophagy.

Rapamycin (sirolimus) and the "rapalog" everolimus and temsirolimus inhibit mTOR by associating with the intracellular protein FKBP12. The FKBP12-rapalog complex binds directly to mTOR and inhibits its functions in the multiprotein complex mTORC1. mTORC2 remains relatively unaffected by mTORC1 inhibitors and can respond by upregulating Akt activity.
CHAPTER 67 PATHWAY-TARGETED THERAPIES

1218 Therapeutic Uses

Cabozantinib is indicated for the treatment of patients with advanced RCC who have received prior antiangiogenic therapy. Cabozantinib was also shown to produce superior efficacy to sunitinib in patients with treatment-naive intermediate- or poor-risk metastatic renal cancer (Choueiri et al., 2016). Also, cabozantinib showed some efficacy in subgroups of patients with lung adenocarcinoma and MET exon 14 splice variants (Paik et al., 2015) and in patients with medullary thyroid cancer.

Adverse Effects

The most commonly reported (<25%) adverse reactions are diarrhea, fatigue, nausea, decreased appetite, PPES, hypertension, vomiting, weight loss, and constipation. Cabozantinib should not be administered to patients with a recent history of bleeding and should be discontinued in patients with GI perforations and fistulas. In the case of thrombotic events such as myocardial infarction, cerebral infarction, or other serious arterial thromboembolic events, treatment with cabozantinib should be discontinued. Blood pressure should be monitored regularly for the onset of hypertension. Due to the risk of fetal harm, women of childbearing age should use contraception during treatment and for 4 months thereafter. Although there are no specific data on this point, nursing mothers are advised to cease breastfeeding during treatment and for 4 months thereafter due to the potential for harm to the infant.

Vandetanib

Mechanism of Action; ADME

Vandetanib is an orally bioavailable, small-molecule multikinase inhibitor of VEGFRs, the EGFR/HER family, RET, BRK, TIE2, and members of the EPH receptor and SRC kinase families. These receptor tyrosine kinases are involved in both normal cellular functions and pathologic processes (Figure 67–2). Vandetanib is a substrate of CYP3A4. Its median elimination half-life is 19 days.

Therapeutic Uses

Vandetanib is indicated for the treatment of symptomatic or progressive medullary thyroid cancer that is unresectable, locally advanced, or metastatic. In patients with asymptomatic or slowly progressing disease, vandetanib is only indicated after careful consideration of the treatment-related risks.

Adverse Effects and Drug Interactions

The most common adverse effects (>20%) are diarrhea, colitis, rash, acneiform dermatitis, hypertension, nausea, headache, upper respiratory tract infections, decreased appetite, and abdominal pain. Less common are QT prolongation, torsades de pointes, and sudden death. Vandetanib should not be used in patients with hepatic impairment or congenital long QT syndrome.

Midostaurin

Midostaurin is a small-molecule multitarget inhibitor with activity against mutant FLT3, a driver in AML. It is FDA-approved for combination chemotherapy of adults with newly diagnosed AML. Leukopenia, nausea, mucositis, diarrhea, and musculoskeletal pain are major adverse effects of treatment. Midostaurin was also approved for different forms of mast cell disorders.

III. Tumor Angiogenesis

Cancer cells secrete angiogenic factors that induce the formation of new blood vessels and guarantee the flow of nutrients to the tumor cells to permit growth and metastasis. Many tumor types overexpress these angiogenic factors, turning on an “angiogenic switch” whereby the tumor cells adopt an invasive phenotype favoring proliferation of endothelial cells and neovascularization. In 1971, Judah Folkman hypothesized that the growth of solid tumors was dependent on angiogenesis and that blockade of the effects of putative angiogenic factors would be a good treatment modality for human cancers (Folkman, 1971). Folkman’s hypothesis proved to be correct and led to the characterization of a number of secreted angiogenic factors, including VEGF, FGF, TGF-β, and PDGF. Furthermore, inhibitors of these angiogenic factors have, indeed, become useful therapeutic agents against certain cancers. VEGF is a major driver of angiogenesis, and inhibitors of VEGF signaling comprise an important class of antitumor agents.

Inhibition VEGF and the VEGFR Pathway

Vascular endothelial growth factor initiates endothelial cell proliferation and vascular permeability when it binds to a member of the VEGFR family, a group of highly homologous receptors with intracellular tyrosine kinase domains; these receptors include VEGFR1 (FLT1), VEGFR2 (KDR), and VEGFR3 (FLT4) (Figure 67–2). The binding of VEGF to its receptors activates the intracellular VEGFR tyrosine kinase activity and initiates mitogenic and antiapoptotic signaling pathways (Nagy et al., 2007). Antibodies targeting VEGF, such as bevacizumab, sterically hinder the interaction of VEGF with its receptor. Aflibercept acts as a VEGF trap; it is a recombinant molecule that uses the VEGFR1-binding domain to sequester VEGF, basically acting as a “soluble decoy receptor” for VEGF. Several small-molecule drugs that inhibit the protein tyrosine kinase function of VEGFR (pazopanib, sorafenib, sunitinib, and axitinib) as well as monoclonal antibodies that target the receptor (ramucirumab) have been approved for clinical use. The inhibition of endothelial function by these different approaches results in a similar spectrum of adverse effects.

Bevacizumab

Mechanism of Action

Bevacizumab is a humanized monoclonal IgG1 antibody that binds to VEGF; the antibody contains the antigen-recognition domain of a murine antibody inserted into a human IgG1. Bevacizumab prevents the interaction of VEGF with its receptors on the surface of endothelial cells and inhibits receptor signaling that normally increases vascular permeability and angiogenesis. Bevacizumab delays progression of renal cell cancer and, in combination with cytotoxic chemotherapy, is approved in the treatment of patients with mCRC as well as NSCLC and glioblastoma.

ADME

Bevacizumab is administered intravenously as a 30- to 90-min infusion every 2 weeks in metastatic colon cancer and, in conjunction with combination chemotherapy, in metastatic NSCLC every 3 weeks with chemotherapy. The antibody has a plasma half-life of about 20 days (range 11 to 50 days).

Therapeutic Use in Cancer

Bevacizumab is indicated as treatment of various cancers, frequently in combination with other drugs. In metastatic colon cancer, bevacizumab combined with FOLFOX or FOLFIRI increases patient survival by about 5 months (Hurwitz et al., 2004). In NSCLC, a combination of bevacizumab with carboplatin and paclitaxel increases survival by about 2 months. Also approved are combinations of bevacizumab with cytotoxic chemotherapy in patients with cervical or ovarian cancer and a combination with IFN-α for the treatment of metastatic RCC. For glioblastoma, bevacizumab is approved as a single agent following prior therapy.

Other Therapeutic Uses: Wet Macular Degeneration

Vascular endothelial growth factor is an important mediator of pathologic vascular permeability. Intravitreal administration of anti-VEGF targeted therapy has become a standard treatment of wet macular degeneration (see also Chapter 69). Bevacizumab and a modified fragment of bevacizumab, ranibizumab, are used. Ranibizumab is derived from the bevacizumab IgG1 by deletion of the Fc domain and changes in six amino acids in the antigen-recognition domain to increase affinity for VEGF. Because these drugs are administered by injection into the vitreous cavity of the eye, few systemic adverse effects are observed. A direct
Aflibercept

Mechanism of Action
Aflibercept (the VEGF trap protein; see discussion that follows) in patients with diabetic macular edema showed that all three treatments improved vision, although aflibercept appeared more effective in patients with worse baseline levels of visual impairment (Wells et al., 2015).

Adverse Effects
Bevacizumab causes a wide range of serious class-related adverse effects that include hypertension, GI perforation, thromboembolic events, and hemorrhage. A major concern is the potential for vessel injury and bleeding in patients with lung cancer. Bevacizumab is contraindicated for patients with a history of hemoptysis, brain metastasis, or a bleeding diathesis. In appropriately selected patients, the predicted rate of life-threatening pulmonary hemorrhage is less than 2%, and for arterial thromboembolism (stroke; myocardial infarction) observed during treatments that include bevacizumab the predicted rate is less than 4%.

Other adverse effects characteristic of drugs that target the VEGF pathway include hypertension and proteinuria. A majority of patients require antihypertensive therapy, particularly those receiving higher doses and more prolonged treatment. Bevacizumab can be associated with congestive heart failure, probably secondary to hypertension, and with reversible posterior leukoencephalopathy in patients with poorly controlled hypertension. GI perforation, a potentially life-threatening complication, has been observed in up to 11% of patients with ovarian cancer. In patients with colon cancer, colonic perforation occurs infrequently during bevacizumab treatment but increases in frequency in patients with intact primary colonic tumors, peritoneal carcinomatosis, peptic ulcer disease, chemotherapy-associated colitis, diverticulitis, or prior abdominal radiation treatment. Perforation of the colon occurs in less than 1% of patients. Following colon cancer surgery, patients on bevacizumab have a higher rate (13% vs. 3.4%) of serious wound-healing complications. Because of the long t1/2 of bevacizumab, elective surgery should be delayed for at least 4 weeks from the last dose of antibody, and treatment should not be resumed for at least 4 weeks after surgery.

Ramucirumab

Mechanism of Action
Ramucirumab is a human IgG1 monoclonal antibody that binds to VEGFR2, blocking the binding of VEGFR ligands and thereby inhibiting ligand-induced activity in endothelial cells.

ADME
Ramucirumab is administered intravenously every 2 to 3 weeks. Its mean half-life is 14 days.

Therapeutic Uses
Ramucirumab is used in combination with chemotherapy for the treatment of patients with mCRC with disease progression on or after prior therapy; as a single agent or in combination with paclitaxel for treatment of patients with advanced gastric adenocarcinoma with disease progression on or after prior chemotherapy; and in combination with docetaxel for treatment of patients with metastatic NSCLC with disease progression on or after chemotherapy.

Adverse Effects
The most common adverse effects are hypertension and diarrhea. Other severe adverse effects overlap with those of bevacizumab (anti-VEGF; see previous discussion): increased risk of hemorrhage, GI perforation, and impaired wound healing.

Afiblercept

Mechanism of Action
Ziv-afiblercept acts as a trap for VEGFR ligands. It is a recombinant fusion protein that contains the extracellular VEGF-binding domain of human VEGFR1/2 fused to the Fc portion of human IgG1. Ziv-afiblercept acts as a soluble receptor that binds to human VEGFR ligands with high affinity (K_d of 0.3 to 40 pM), reducing their plasma concentrations to levels that are too low for significant activation of their cognate receptors.

ADME
The elimination half-life is about 6 days (range 4–7 days). Ziv-afiblercept is administered by intravenous infusion over 1 h every 2 weeks.

Therapeutic Uses
In combination with FOLFIrI, afiblercept is indicated for patients with mCRC that is resistant to or has progressed following an oxaliplatin-containing regimen.

Adverse Effects
The most common adverse effects are hypertension and diarrhea. Other severe adverse effects overlap with those of bevacizumab (anti-VEGF; see previous discussion): increased risk of hemorrhage, GI perforation, and impaired wound healing.

Antiangiogenic Small-Molecule Kinase Inhibitors

Sunitinib

Mechanism of Action
Sunitinib is a small-molecule, orally bioavailable inhibitor of multiple kinases, including VEGFR2.

ADME
The typical treatment cycle of sunitinib is 4 weeks on treatment followed by 2 weeks off. The dosage and schedule of sunitinib can be decreased in patients with adverse effects. More recently, a 2-week on/1-week off schedule has proven to be better tolerated and as effective as the original treatment schedule. Sunitinib is metabolized by CYP3A4 to produce an active metabolite, SU12662, the t1/2 of which is 80–110 h; steady-state levels of the metabolite are reached after about 2 weeks of repeated administration of the parent drug. Further metabolism results in the formation of inactive products. The pharmacokinetics of sunitinib are not affected by food intake.

Therapeutic Uses
Sunitinib has activity in metastatic renal cell cancer, producing a higher response rate and a longer progression-free survival than seen with IFN or bevacizumab. Sunitinib is also approved for the treatment of pancreatic NETs and of GIST in patients who have developed resistance to imatinib as a consequence of c-KIT mutations. Specific c-KIT mutations correlate with the degree of response to sunitinib (e.g., patients with c-KIT exon 9 mutations have a response rate of 37%; patients with c-KIT exon 11 mutations have a 5% response rate).

Adverse Effects
The main adverse effects of sunitinib are shared by all antiangiogenic inhibitors: bleeding, hypertension, proteinuria, and, uncommonly, arterial thromboembolic events and intestinal perforation. However, because sunitinib is a multitargeted TKI, it has a broader adverse effect profile than bevacizumab. Fatigue affects 50%–70% of patients and may be disabling. Hypothyroidism occurs in 40%–60% of patients. Bone marrow suppression and diarrhea also are common side effects; severe neutropenia (neutrophils < 1000/mL) develops in 10% of patients. Less common side effects include hepatotoxicity, congestive heart failure and PPES. It is essential to check blood counts and thyroid function at regular intervals. Periodic echocardiograms also are recommended.

Sorafenib

Mechanism of Action and Therapeutic Use
Sorafenib, like sunitinib, is an orally bioavailable inhibitor of multiple protein kinases. Sorafenib is the only drug currently approved for treatment of patients with hepatocellular carcinoma. Sorafenib also is approved in patients with metastatic renal cell cancer, but sunitinib and pazopanib are generally preferred first-line therapies (see previous discussion and below).

ADME
Sorafenib is given orally every day without treatment breaks. Sorafenib is metabolized to inactive products by CYP3A4 with a t1/2 of 20–27 h; with repeated administration, steady-state concentrations are reached within 1 week.
1220 Adverse Effects
Sorafenib-treated patients can experience the vascular toxicities seen with other antiangiogenic medications described under bevacizumab. More common adverse effects include fatigue, nausea, diarrhea, anorexia, rash, and palmar-plantar erythrodysesthesia; uncommonly, bone marrow suppression, GI perforation, and cardiomyopathy occur.

Pazopanib
Pazopanib is a kinase inhibitor of VEGFR-1, -2, and -3 as well as FGFRs, KIT, LCK, PDGFR, and other kinases implicated in pathologic angiogenesis and cancer progression. Pazopanib is approved for the treatment of patients with advanced renal cell cancer and advanced STS after prior chemotherapy. It has less toxicity and equivalent efficacy to sunitinib in patients with treatment-naive metastatic renal cancer and therefore has become the preferred first-line treatment of many patients. Pazopanib is orally bioavailable, metabolized mostly by CYP3A, and eliminated with a \( t_{1/2} \) of 31 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, GI perforation, QT prolongation, and cardiomyopathy. Pazopanib carries a black-box warning: It can produce severe and life-threatening hepatotoxicity; as a consequence, pazopanib should not be used in elderly patients or those with preexisting liver function test abnormalities.

Other Receptor Kinase Inhibitors With Antiangiogenic Effects
Axitinib is a kinase inhibitor of VEGFR-1, -2, and -3 that are implicated in pathologic angiogenesis, tumor growth, and cancer progression. Axitinib is approved for the treatment of patients with advanced RCC after failure of one prior systemic therapy. Axitinib is orally bioavailable, metabolized mainly by CYP3A/5, and eliminated with a \( t_{1/2} \) of 2.5 to 6.1 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, and GI perforation similar to those of the anti-VEGF bevacizumab (see previous discussion).

Lenvatinib inhibits the protein kinase activities of VEGFR-1, -2, and -3 as well as FGFRs, PDGFR, and other kinases that are implicated in pathologic angiogenesis and cancer progression. Lenvatinib is approved for the treatment of patients with recurrent or metastatic differentiated thyroid cancer and in combination with everolimus for patients with advanced renal cell cancer. Lenvatinib is orally bioavailable, metabolized by CYP3A, and eliminated with a \( t_{1/2} \) of 28 h. Major adverse effects include hypertension, thrombotic and hemorrhagic events, hepatotoxicity, GI perforation, and QT prolongation.

Regorafenib inhibits the protein kinase activities of RET, VEGFR1-3, KIT, PDGFR, FGFR1/2, TIE2, RAF1, BRAF, and ABL at concentrations that can be achieved clinically. Several of these kinases are implicated in pathologic angiogenesis and malignant progression. Regorafenib is approved for the treatment of patients with mCRC after previous chemotherapy, anti-VEGF therapy, or anti-EGFR therapy and for patients with locally advanced, unrespectable, or metastatic GIST after imatinib or sunitinib. Regorafenib is orally bioavailable, metabolized mostly by CYP3A, and eliminated with a \( t_{1/2} \) of about 28 h (range 14 to 58 h). Major adverse effects include hepatotoxicity, hypertension, thrombotic and hemorrhagic events, GI perforation, QT prolongation, and wound-healing complications. As expected for an agent metabolized by CYP3A4, strong inducers and strong inhibitors of CYP3A4 must be avoided (see pathobiology, previously discussed, for details).

IV. Targeting the Immune System

Immune Checkpoint Inhibitors
Recent striking successes of cancer immunotherapy have given credence to the long-held hope that the immune system may be unleashed to treat cancer. The conceptual breakthrough is based on the discovery of inhibitory signals that limit T-cell activation, so-called immune checkpoints. The discovery of receptors, ligands, and their function in the control of immune cell activity during the past two decades led to the development of clinically effective monoclonal antibodies that enable T cells to recognize and eradicate cancer cells with acceptable adverse effects (Figure 67–5).

HISTORY Immune Checkpoint Inhibitors
The discovery of the TCR and of costimulatory signal pathways in the period from 1982 to 1992 defined essential requirements for T-cell activation during antigen presentation: In addition to the antigen-TCR interaction, CD28 on T cells binds to B7 proteins on APCs (see Figure 67–5, see also Figures 35–2 and 35–4). The finding, in the mid-1990s, of co-inhibitory molecules that can dampen T-cell activation revealed a potential mechanism for drugs to modulate immune checkpoints and alter antitumor immune activity. TCR activation induces expression of the inhibitory CTLA-4, a CD28 homolog with higher affinity for the B7 ligands than CD28. CTLA-4 inhibits T-cell activation to control autoimmune tissue damage. PD-1, another inhibitory molecule expressed on T cells after their activation, and PD-L1, the ligand for PD-1, were described in the early 2000s. It became obvious that T cells present in human tumors were being inhibited by factors in the tumor tissues: TILs harvested from patients and activated exogenously showed efficacy and paved the way for targeting immune inhibition. Improved survival of patients with metastatic melanoma after anti–CTLA-4 treatment led to FDA approval of ipilimumab in 2011; anti-PD-1 and anti-PD-L1 were approved in 2014. Clinical trials in multiple types of cancer have been ongoing since then and have led to the approval of immune checkpoint inhibitors for additional indications (Monteiro, 2015) described in this section.

Mechanisms of T-Cell Activation
Antigen-mediated activation of T cells is initiated by engagement of the TCR with antigen presented on MHC protein on the surface of an APC, "signal 1." In addition, engagement of CD28 costimulatory molecules on T cells is required for effective T-cell activation that includes cell proliferation, migration, and production of cytokines. This "signal 2" is provided by B7 surface proteins on APCs, for example, CD80 or CD86 (Figures 35–4 and 67–5). T-cell activation is tightly controlled by immune-suppressive cells and cytokines as well as by coinhibitory molecules present on T cells, such as CTLA-4 or PD-1 (Figure 67–5). CTLA-4 is expressed by activated CD4 and CD8 T cells and competes with costimulatory CD28 for binding to the B7 protein ligands. Binding of CTLA-4 to B7 proteins interrupts the initial CD28 costimulatory signals and serves as an early negative regulator of the T-cell activation responses, that is, an immune checkpoint. Additional control of T-cell activity is provided by later inhibitory signals through other molecules, such as PD-1 that binds the ligand PD-L1. PD-1 is mainly expressed by activated CD4 and CD8 T cells as well as APCs.

Blocking monoclonal antibodies to CTLA-4, PD-1, or PD-L1 are currently used to neutralize co-inhibitory receptors during T-cell priming (CTLA-4), to maintain cancer antigen-specific T-cell function, and to provide a sustained T-cell response (PD-1) that includes increased production...
Mechanism of Action
Iplilimumab blocks the interaction of CTLA-4 with B7 ligands on APCs and thereby augments T-cell activation (Figure 67–5). Inhibition of CTLA-4 signaling can also inhibit regulatory T-cell function that dampens cytotoxic T-cell activity and thus increases the antitumor immune response further (Mellman et al., 2011).

ADME
Iplilimumab is administered intravenously and shows linear pharmacokinetics in the dose range of 0.3 to 10 mg/kg, with a terminal half-life of 15.4 days.

Therapeutic Uses
A pivotal 2010 trial in patients with metastatic melanoma showed improved median overall survival after ipilimumab treatment (Hodi et al., 2010). This trial led to FDA approval of ipilimumab for the treatment of metastatic melanoma. Further studies showed that some patients had clinical responses that lasted for 10 or more years (Schadendorf et al., 2015). The tumor response can take several months to manifest, and tumors may increase in size during this period, in part due to the evolving inflammatory reaction (Mellman et al., 2011). Current recommended dosing of ipilIMUMab is 3 mg/kg intravenously over 90 min every 3 weeks for a total of four doses for patients with metastatic disease and 10 mg/kg followed by 10 mg/kg every 12 weeks for up to 3 years or until documented disease recurrence or unacceptable toxicity for patients treated in the adjuvant setting.

Adverse Effects
Blockade of CTLA-4 compromises immune tolerance to some normal tissue antigens and provokes inflammatory toxicities, mostly in the skin, pituitary gland, intestine, and liver. The activation of T-cell responses by ipilimumab treatment leads to immune-related toxicities in the majority of patients (73.6%), with 18.6% reaching toxicity grade 3–4 toxicity (Callahan et al., 2016). Adverse effects on the skin (pruritus, rash, vitiligo) and GI tract (diarrhea, colitis) are the most frequent, whereas immune-mediated hepatitis, hypophysitis, and hypo- or hyperthyroidism are less frequent. Withholding treatment because of moderate adverse reactions until return to baseline and high-dose corticosteroids for severe immune-mediated reactions are recommended.

Other Drugs in This Class
Tremelimumab (formerly ticilimumab) is a fully human IgG2 monoclonal antibody that targets CTLA-4; it is under investigation in several clinical trials.

Inhibitors of Programmed Cell Death 1 (PD-1)
Activation of the PD-1 checkpoint pathway in T cells by PD-L1 or PD-L2 evokes a negative regulatory immune response and inactivates T cells (Figure 67–5). Tumor cells can exploit this pathway by presenting the PD-L1 ligand to tumor-infiltrating T cells and thus shield the tumor from T-cell–mediated destruction. Presentation of PD-L1 to activated T cells results in T-cell exhaustion, whereas antibody-mediated blockade of PD-L1 can restore or maintain T-cell antitumor response.

Nivolumab
Mechanism of Action
Nivolumab is a fully human monoclonal IgG4 antibody that blocks the interaction between PD-1 and its ligands.

ADME; Clinical Use
Nivolumab is administered as an intravenous infusion every 2 weeks until the time of disease progression or of unacceptable toxicity. The drug has an elimination half-life of 26.7 days. Nivolumab is FDA approved for the treatment of a variety of cancers, currently including advanced melanoma, previously treated advanced NSCLC, RCC, advanced head and neck cancer, and relapsed/refractory classical Hodgkin lymphoma. Quite strikingly, nivolumab provided an overall response rate of 87% in patients with...
Hodgkin lymphoma who had failed treatment with brentuximab vedotin (see discussion that follows). Nivolumab has significant clinical activity in a variety of heavily pretreated patients with solid tumors as well as patients with hematological malignancies. This is also true for the other anti–PD-1 monoclonal antibody, pembrolizumab.

**Adverse Effects**
The most common adverse effect of treatment in patients with melanoma is a rash (>20%); in patients with advanced squamous NSCLC, the adverse effects are fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, and constipation. Immune-mediated adverse reactions are much less common than with CTLA-4 antibodies; corticosteroids are recommended based on the severity of the reaction. For pneumonitis, colitis, hepatitis, nephritis and renal dysfunction, withhold treatment if the adverse effects are moderate and discontinue treatment if the effects are severe.

**Pembrolizumab**
Pembrolizumab (formerly called lambrolizumab or MK-3475) is a humanized monoclonal IgG4κ isotype antibody that blocks interaction between PD-1 and its ligands. This humanized antibody has a mouse variable region grafted onto a human antibody framework and shows high affinity toward PD-1 receptors of humans and other primates but no appreciable affinity for mouse or rat PD-1.

The FDA has extended the approval for pembrolizumab to any cancer with mismatch repair (MMR) deficiency or high microsatellite instability (MSI-H). The defects in DNA repair lead to a higher mutation load and increased generation of mutant protein antigen by cancer cells that can activate the immune system. This first cancer tissue-agnostic approval extends immune checkpoint inhibitor treatment to subsets of patients with hereditary CRC due to Lynch syndrome (MSI-H) and up to 20% of patients with sporadic colon cancer. The frequency is less in endometrial, ovarian and pancreatic cancers and will require testing of each patient’s tumor to assess suitability of the treatment.

**ADME: Clinical Use**
The recommended treatment schedule for pembrolizumab is 2 mg/kg (or a 200-mg flat dose) as an intravenous infusion over 30 min every 3 weeks. The elimination half-life is 26 days. In clinical trial, pembrolizumab demonstrated an overall response rate of 26% in patients with ipilimumab-pretreated and refractory advanced melanoma (Hamid et al., 2013; Robert et al., 2014). Pembrolizumab is more effective and less toxic than ipilimumab in patients with either treatment-naive or BRAF inhibitor–pretreated melanoma. Pembrolizumab is currently approved for the treatment of patients with advanced melanoma, unresectable or metastatic melanoma in patients previously treated with ipilimumab, PD-L1–positive NSCLC (either prior to or after platinum-containing chemotherapy), and chemotherapy-refractory head and neck cancer. Significant antitumor activity has also been found relative to chemotherapy in patients with metastatic urothelial cancer, Merkel cell carcinoma, and Hodgkin lymphoma.

**Adverse Effects**
The most common adverse effects, experienced by more than 20% of patients, are fatigue, cough, nausea, pruritus, rash, decreased appetite, constipation, arthralgia, and diarrhea. An additional 10% of patients may experience complications with infections. Serious adverse events include immune-mediated inflammation, specifically pneumonitis, colitis, hepatitis, and hypophysitis and both hyper- and hypothyroidism. Withholding treatment and administration of systemic corticosteroids for grade 2 or discontinuing treatment with more severe adverse effects is recommended. Because human IgG4 can cross the placenta, the benefit from pembrolizumab treatment should be balanced with the potential fetal risk in a pregnant woman.

**Antagonists of PD-1 Ligand 1**
Programmed cell death 1 has two ligands, PD-L1 and PD-L2, each with distinct expression profile. The PD-L1 ligand is expressed on APCs, T cells, B cells, and nonhematopoietic cells, which can include cancer cells (Figure 67–5). Expression of PD-L2 is restricted to APCs, macrophages, myeloid dendritic cells, and mast cells. Clinical trial results are promising with drugs targeting PD-L1.

**Atezolizumab**
Mechanism of Action
Atezolizumab, also known as MPDL3280A, is a fully human IgG1 monoclonal antibody that blocks the interaction of PD-L1 with PD-1 and B7-H1. PD-L1 is expressed in many cancers and thus can suppress the activation of cytotoxic T cells that enter the tumor. Atezolizumab can remove this inhibitory effect and promote an effective antitumor response.

**ADME**
Atezolizumab is administered as an intravenous infusion over 60 min every 3 weeks. The terminal half-life is 27 days.

**Clinical Use**
Atezolizumab is indicated for conventional treatment-resistant metastatic NSCLC as well as locally advanced or metastatic urothelial cancer.

**Adverse Effects**
The most common adverse effects in 20% or more of patients with metastatic NSCLC are fatigue, decreased appetite, dyspnea, cough, nausea, musculoskeletal pain, and constipation. Patients with urothelial carcinoma may report urinary tract infection. Possible immune-related adverse effects include hepatitis, colitis, hypophysitis, thyroid disorders, adrenal insufficiency, type 1 diabetes mellitus, pancreatitis, myasthenia gravis, Guillain-Barré syndrome, and ocular inflammation; these may require discontinuation of treatment. Due to potential embryo-fetal toxicity, female patients should be advised accordingly.

**Other Anti–PD-L1 Antibodies**
Durvalumab (approved in 2017 for metastatic urothelial cancer) and avelumab (approved in 2017 for metastatic urothelial and Merkel cell cancer) are also being evaluated for efficacy toward cancers of the head and neck, stomach, lung, and ovary, as well as hepatocellular cancer.

**Combination of Anti–PD-1 and Anti–CTLA4**
Because anti–CTLA-4 and anti–PD-1 target distinct immune checkpoints during T-cell activation, preclinical studies have shown that concurrent targeting of CTLA-4 and PD-1 significantly improves therapeutic efficacy when compared to effects of single agents (Curran et al., 2010). In patients with advanced melanoma, the combination of ipilimumab and nivolumab produces a positive response in more than 50% of the patients with an acceptable level of adverse effects, although the combination therapy significantly increased the rate of rare but fatal myocarditis (combination 0.17%; nivolumab < 0.01%) (Johnson et al., 2016). The 1- and 2-year overall survival rates were 94% and 88%, respectively (Wolchok et al., 2013). Thus, combinations of immune checkpoint inhibitors with different targets may become the standard of care in various solid as well as hematologic malignancies (Mellman et al., 2016). Most important, combination immunotherapy will likely be more effective than most other forms of treatment of patients with metastatic disease (Restifo et al., 2016).

**Cytokines to Stimulate Immune Responses**

**Interleukin 2**
Of the 70 or so proteins and glycoproteins that are classified as cytokines, only IFN (Chapters 34 and 35) and IL-2 are in routine clinical use, often for actions against cancer.

Activated CD4+ T cells are the primary producers of IL-2. The functions of IL-2 are myriad; amongst other roles, IL-2 promotes the growth of T cells and NK cells, stimulates the proliferation of and antibody production by B cells, and drives the development of Treg cells (mediators
Mechanism of Action
Interleukin 2 stimulates the proliferation of activated T cells and the secretion of cytokines from NK cells and monocytes. IL-2 stimulation increases cytotoxic killing by T cells and NK cells.

Interleukin 2 is a 133–amino acid glycoprotein (molecular weight ~ 15 kDa) produced by activated T cells and NK cells; it promotes activated T-cell proliferation and enhanced killing by NK cells. Responsiveness depends on expression of the IL-2R. The receptor comprises three independently expressed membrane monospans, α, β, and γ, which can assemble in several combinations to produce working receptors of varying affinities. These monospans are variously expressed in lymphohematopoietic cells, lack C-terminal protein kinase activities, and transduce signals via coupling to Jak proteins (Figure 67–6). Nearly all types of tumor cells lack receptor expression and are unresponsive to IL-2.

ADME
Interleukin 2 (as recombinant IL-2, aldesleukin) is administered intravenously. The serum t½ of IL-2 after intravenous administration has an α phase of about 15 min and a β phase of about 90 min. IL-2 is excreted in the urine as an inactive metabolite.

Therapeutic Uses
Aldesleukin possesses the biological activities of native human IL-2. The drug is approved for use in patients with metastatic renal cell cancer and metastatic melanoma. High-dose IL-2 produces an overall response rate of 15%–25% in patients with renal cell cancer; 8% achieve a complete response. In patients with metastatic melanoma, high-dose IL-2 induces an overall response rate of 16%–22%, and 6% achieve a complete response. In both instances, responses last a median of about 5 years. Low-dose IL-2 also produces responses, but few are complete responses, and the duration may be less than with high-dose IL-2.

Adverse Effects
Interleukin 2 toxicities are dominated by the capillary leak syndrome, in which intravascular fluid leaks into the extravascular space, producing hypotension, edema, respiratory difficulties, confusion, tachycardia, oliguric renal failure, and electrolyte problems. Symptoms include fever, chills, malaise, nausea, vomiting, and diarrhea. Laboratory abnormalities include thrombocytopenia, abnormal liver function tests, and neutropenia. Most patients develop a pruritic skin rash. Hypothyroidism may occur. Arrhythmias are a rare complication. These toxicities can be life threatening, yet nearly all are reversible within 24–48 h of discontinuing therapy. Patients should have normal renal and hepatic function before beginning therapy and should be closely supervised in an inpatient facility capable of care at the intensive care unit level during drug administration.

Figure 67–6 A pharmacologist’s view of IL-2 receptors, their cellular signaling pathways, and their inhibition. A. IL-2 receptors. The IL-2 receptor has three components: an α chain, a 55-kDa protein (CD25) involved mainly in IL-2 binding; a β chain, a 75-kDa protein that binds to Jak1; and a γ chain, a 64-kDa protein that signals via Jak3. These components combine as shown to produce receptors of varying affinities and with different capacities for intracellular signaling. The γ chain is a component of many cytokine receptors (IL-2, IL-4, IL-7, IL-9, IL-15, and IL-21). Resting T cells have a low density of IL-2Rα; however, activation of the TCR (see Figure 35–2) and IL-2, itself, induce IL-2Rα expression. IL-2Rα can also be induced by a large variety of cytokines, viruses, and activators of PKC. The β and γ monospans are constitutively expressed on many lymphohematopoietic cells, and their expression can also be regulated. Tumor cells generally lack receptor expression and are unresponsive to IL-2.

B. IL-2 receptor signaling. The formation of the quaternary complex of IL-2 and the α, β, and γ units of IL-2R suffice to activate intracellular signaling. The IL-2R monospans shown in A lack the protein tyrosine kinase activity common to many monospanning hormone receptors. Rather, these receptors respond to IL-2 binding at the extracellular domain by differentially recruiting Jak1 and Jak3 to their cytokolic domains, Jak1 at IL-2Rβ and Jak3 at IL-2Rγ. Heterodimerization of β and γ cytokolic domains leads to activation of Jak1 and Jak3. The Jaks transactivate and also phosphorylate key tyrosines on IL-2Rβ. These phosphotyrosines (P) permit important protein-protein interactions that direct downstream signaling:

- Binding of an SHC adapter/scaffolding protein that is the platform for activation of the Ras–MAPK pathway and the PI3K pathway
- Recruitment and phosphorylation of STAT5 (and to a lesser extent, STATs 1 and 3), leading to STAT-dependent gene regulation

IL-2/IL-2R signaling can be therapeutically reduced by inhibitors that interact with IL-2Ra, Jak1, and Jak3 (red boxes and T bars).
CHAPTER 67
PATHWAY-TARGETED THERAPIES

Cancer Vaccines

Vaccination against cancer antigens has shown little efficacy with the exception of two approaches that were approved by the FDA in 2010 (sipuleucel-T) and in 2015 (T-VEC).

Sipuleucel-T

Sipuleucel-T is a cell-based approach designed to induce an immune response against PAP, which is expressed in most prostate cancers. This autologous cellular immunotherapy is generated from a patient’s peripheral blood cells, which are isolated by leukapheresis. The cells are exposed to a human recombinant protein, PAP–GM-CSF. APCs present amongst the blood cells are thought to take up and process PAP and direct the immune response toward the antigen. A patient receives the treated cells by infusion on three occasions at 2-week intervals. Treatment is approved for patients with minimally symptomatic, hormone-refractory, metastatic prostate cancer. Adverse effects include acute infusion reactions, which can be reduced by premedication with acetaminophen and antihistamine.

T-Vec

T-VEC (talimogene laherparepvec) is an oncolytic herpesvirus that replicates within tumors and expresses GM-CSF. Tumor antigens are released after virally induced cell death, and the presence of GM-CSF can promote an antitumor immune response. T-VEC is approved for the local treatment of unresectable cutaneous and nodal lesions in patients with melanoma. T-VEC may synergize with immune checkpoint inhibitor treatment. Adverse effects are influenza-like symptoms and injection site pain.

Chimeric Antigen Receptor T Cells

Treatment of patients with B-cell leukemias or lymphomas with receptor-engineered T cells has produced striking successes. CARs contain the antigen-binding domain of a monoclonal antibody to confer recognition of the targeted tumor antigen coupled to intracellular domains capable of activating T cells (Figure 67–7). When expressed in T cells, these CARs recognize cell surface antigens and activate T cells independent of antigen presentation by a MHC molecule as required for physiologic antigen presentation (see Figures 35–2 and 67–5). In initial studies, CAR-expressing T cells were targeted to NY-ESO-1, a tumor antigen of the cancer/testis family that is highly expressed on many poor-prognosis melanoma cells. The CAR T cells showed long-lasting efficacy (>3 years) in some patients with metastatic melanoma. CAR targeting CD19, a B-cell antigen, also resulted in striking efficacy in patients with B-cell leukemias (Kedaroff et al., 2016). The approval of CD19 CAR-T cells (tisagenlecleucel-T; previously named CTL019) has been recommended, based on data showing >80% remissions of relapsed or refractory B cell ALL during treatment. Other CARs targeting CD22 and B-cell maturation antigen (BCMA) have shown efficacy and are currently under investigation.

Future Challenges of Immunotherapy

The potential for immunotherapies to augment conventional chemotherapy, pathway-targeted treatment, and radiotherapy will require detailed exploration and will be a common theme in the design of future clinical trials (Ebert et al., 2016; Hughes et al., 2016). The recent identification of multiple negative and positive immune-modulatory pathways that can be targeted is leading to development of new drugs that will require testing as monotherapy and combination with each other as well as with conventional treatments. This new class of cancer treatment presents a new set of adverse effects (e.g., fulminant myocarditis caused by a combination of immune checkpoint inhibitors; Johnson et al., 2016) that must be understood mechanistically before rational combination strategies can be developed.

V. Other Targets

Inhibitors of Poly (ADP-Ribose) Polymerase

DNA damage-repair genes are frequently inactivated in human cancer. PARP1 is the product of one such gene. PARP1 is a nuclear protein that transfers ADP-ribose from NAD+ to target proteins, and this poly (ADP-ribosyl)ation (or PARylation) of nuclear proteins by PARP1 plays a significant role in the DNA damage response (Tállis et al., 2014). Inactive PARP1 associates with chromatin and helps to create a compact chromatin structure in the nucleosome. DNA damage (e.g., strand breaks) mobilizes the enzyme, promoting PARP-mediated PARylation, with the result that chromatin relaxes in the area of damage. The mechanisms of relaxation are the PARylation of PARP1 itself, and of histones and other chromatin-associated proteins, resulting in their dissociation from DNA. PARylation produces branching chains up to 200 ADP-ribose units in length. These chains provide docking centers for the localized recruitment of PAR-binding factors and thence of DNA repair enzymes (e.g., DNA polβ, DNA ligase III) and proteins that help to maintain an inactive environment in the open chromatin region while repairs are made to the damaged DNA. The synthesis and degradation of PAR chains in vivo is tightly regulated, with the chains having half-lives measured in minutes (Wei and Yu, 2016). Excessive activation of PARP1 leads to depletion of the cellular pool of NAD+ and to cell death; teleologically, this could be viewed as a means of preserving genomic integrity by removing cells with heavily damaged DNA.

Deficient PARP1 activity leads to defective DNA repair. However, PARP-deficient cells are still able to carry out DNA repair through a different mechanism: homologous recombination. The protein machinery for homologous recombination repair includes the breast cancer susceptibility genes BRCA1 and BRCA2, suggesting that cells with diminished or absent BRCA1/2 function could be unusually susceptible to the inhibition of PARP activity. BRCA1/2 mutations predispose carriers to breast, ovarian, and other cancers that can be resistant to chemotherapy. BRCA-deficient cells are more dependent on PARP1 and base excision repair to maintain genomic integrity. BRCA1/2-deficient cancer cells are less able to carry out repair and ultimately die; inhibition of PARP could accelerate this process. It is noteworthy that PARPs catalyze PARylation of a number of proteins that regulate cellular processes beyond DNA damage repair; these extra-chromatin actions may contribute to the clinical efficacy and adverse effects of PARP inhibitors. Inhibitors of PARP are designed to compete with NAD+ at its binding site on the PARP enzyme. Olaparib andrucaparib are approved for the treatment of patients with advanced ovarian cancer.
**Olaparib**

Olaparib is an orally bioavailable inhibitor of PARP enzymes.

**ADME**

Olaparib is rapidly absorbed after oral administration and metabolized primarily by CYP3A4, yielding a t\(_{1/2}\) of about 12 h. Drug exposure is increased or reduced when administered in combination with a CYP3A4 inhibitor or inducer, respectively.

**Therapeutic Uses; Adverse Effects**

Olaparib is EMA and FDA approved as monotherapy in patients with germline BRCA-mutated, advanced, ovarian cancer who have been treated with three or more prior lines of chemotherapy. Adverse effects include GI upset (nausea and vomiting) and loss of appetite; fatigue; muscle and joint pain; low blood cell counts and anemia; and occasionally leukemia. Potentially fatal MDS and pneumonitis have been observed.

**Rucaparib**

Rucaparib is a benzimidazole derivative that inhibits PARP1. Rucaparib is FDA approved for treatment of advanced ovarian cancer in patients exhibiting deleterious BRCA mutations who have been treated with at least two prior chemotherapies. The drug was approved in conjunction with the approval of a gene-sequencing test that detects BRCA1/2 mutations in patient tumor tissue.

**Clinical Use; Adverse Effects**

The drug is administered orally but should not be given until the patient has recovered from any hematological toxicity caused by previous chemotherapy. CYP2D6 metabolizes rucaparib, yielding a half-life of about 18 h. Adverse effects include GI upset and abdominal pain, fatigue, and decreased appetite. MDS and AML are rare but serious adverse effects (<1%). This agent may cause fetal harm and should not be administered to pregnant females or used by nursing mothers.

**BCL2 Inhibitors**

The BCL2 protein family comprises more than 20 proteins that govern mitochondrial outer membrane permeabilization and control programmed cell death (apoptosis). Proteins in this family can be either pro- or antiapoptotic depending on their content of BCL2 homology domains (BH1 to 4). Proapoptotic proteins contain a BH3 domain that is necessary for dimerization with other proteins of the BCL2 family. Antiapoptotic proteins contain BH1 and BH2. The balance of these interacting proteins controls mitochondrial outer membrane permeabilization, cytochrome c release, and the activation of caspases that leads to apoptosis (Figure 67–8). BCL2 promotes cellular survival by inhibiting proapoptotic proteins like BIM, BAX, and BAK and is overexpressed in CLL and some other tumors where it can support tumor cell survival and resistance to cancer treatments.

**Venetoclax**

**Mechanism of Action**

Venetoclax is a first-in-class, orally bioavailable, small-molecule inhibitor of BCL2. It was designed as a BH3 mimic that inhibits BCL2 interaction with the proapoptotic BH3-only family members, such as BIM, BID, and BAD. In vitro, venetoclax inhibits BCL2 action with an IC\(_{50}\) of less than 0.01 nM and with a selectivity of two to three orders of magnitude over other BCL2 family members. In the presence of venetoclax, BH3-only proteins can translocate to mitochondria and initiate BAX/BAK-dependent apoptosis. Overexpression of BCL2 occurs in CLL cells, where it supports tumor cell survival and resistance to chemotherapeutic agents. Thus, venetoclax helps restore apoptosis in these cells.

**ADME; Therapeutic Use; Adverse Effects**

Oral absorption is significantly improved 3- to 5-fold by administration with a meal. Venetoclax, a Pgp substrate, is metabolized by CYP3A4/5; concomitant use of CYP3A inhibitors or inducers and Pgp inhibitors should be avoided (see previous discussion of palbociclib for details). The elimination half-life is 18–26 h. Venetoclax is approved for the treatment of patients with CLL with a 17p deletion. The most common adverse effects are neutropenia, diarrhea, nausea, anemia, upper respiratory tract infection, thrombocytopenia, and fatigue. Venetoclax should not be administered during pregnancy or breastfeeding until further data are available.

**Thalidomide and Lenalidomide**

Thalidomide and lenalidomide have a most unusual history and a multiplicity of biological and immunological effects. Thalidomide originally was used for the treatment of pregnancy-associated morning sickness.

![Figure 67–8](https://example.com/figure67-8.png)  
**Figure 67–8**  
BH3 mimetics enhance apoptosis. Permeability of the outer mitochondrial membrane to cytochrome c is regulated by proteins required for forming pores, including proapoptotic BAX and BAK. BAX and BAK are rendered inactive by binding to the BH3 domains of antiapoptotic proteins such as BCL2. BH3 mimetic drugs (venetoclax) target BCL2 and its interaction with BAX/BAK, reducing the inhibitory effect of BCL2 on apoptosis progression, enhancing cytochrome c release, and sensitizing the cell to apoptosis. Cancer cells may be resistant to apoptosis by overexpression of BCL2. BH3 mimetics such as venetoclax release the resultant blockade and promote apoptosis.
but was withdrawn from the market due to teratogenicity and dysmelia (stunted limb growth). It reentered clinical practice for treatment of erythema nodosum leprosum (see Chapter 60). Further research revealed its antiangiogenic and immunomodulatory effects. At least four distinct mechanisms have been proposed to explain its antitumor activity, which are summarized in Figure 67–9 and enumerated in its legend.

Both thalidomide and lenalidomide possess potent activity in patients with newly diagnosed and heavily pretreated relapsed/refractory MM. Lenalidomide also is approved for its activity in the Sq− subset (or del[5q] subset) of MDS. A specific gene array profile identifies patients with MDS who lack the Sq− abnormality but respond to lenalidomide. A more recently added derivative of thalidomide is pomalidomide, approved for treatment of patients with MM resistant to lenalidomide.

### Thalidomide

**ADME**

Thalidomide exists at physiological pH as a racemic mixture of cell-permeable and rapidly interconverting nonpolar S(−) and R(+) isomers. The R-enantiomer is associated with the teratogenic and biological activities, while the S accounts for the sedative properties of thalidomide. In treating MM, doses usually are escalated by 200 mg/d every 2 weeks until dose-limiting side effects (sedation, fatigue, constipation, or a sensory neuropathy) appear. With extended treatment, the neuropathy may necessitate dose reduction or discontinuation of treatment for a period of time. Thalidomide absorption from the GI tract is slow and highly variable. It distributes throughout most tissues and organs, without significant binding to plasma proteins. The enantiomers are eliminated with a t1/2 of about 6 h, mainly due to spontaneous hydrolysis in all body fluids; the S-enantiomer is cleared more rapidly than the R-enantiomer. Thalidomide and its metabolites are excreted in the urine, while the nonabsorbed portion of the drug is excreted unchanged in feces. The inactive hydrolysis products undergo CYP-mediated metabolism. Longer plasma t1/2 is reported at the highest doses (1200 mg daily). No dose adjustment is necessary in the presence of renal failure.

**Lenalidomide**

Lenalidomide constitutes the lead compound of immunomodulatory thalidomide derivatives. Lenalidomide induces the ubiquitination and degradation of target proteins by the E3 ubiquitin ligase CRL4CRBN (Fink and Ebert, 2015). Target proteins in MM cells are IKZF1/3, which are crucial for cell survival (Lu et al., 2014) (Figure 67–9). In MDS, casein kinase 1A1 is the target protein (Kronke et al., 2015). Cellular effects of lenalidomide include direct suppression of tumor cell growth in culture, T-cell and NK-cell activation, suppression of TNFα and other cytokines, angiogenesis, and promotion of HSC differentiation.

**ADME**

The standard dosage of lenalidomide is 25 mg/d for 21 days of a 28-day cycle. The drug is rapidly absorbed following oral administration, reaching peak plasma levels within 1.5 h. The t1/2 of parent drug in plasma is 9 h. Approximately 70% of the orally administered dose of lenalidomide is excreted intact by the kidney. Dose adjustments to 10 mg/d for creatinine clearance of 30–50 mL/h and to the same dose every 2 days for creatinine clearance less than 30 mL/h are recommended for patients with renal failure.

**Therapeutic Use**

Lenalidomide exhibits potent antitumor activity in MM, MDS, and CLL; this agent causes fewer adverse effects and lacks the teratogenicity of thalidomide.

**Adverse Effects of Thalidomide and Lenalidomide**

Thalidomide is well tolerated at doses less than 200 mg daily. Common adverse effects are sedation and constipation. The most serious adverse effect is peripheral sensory neuropathy, which occurs in 10%–30% of patients with MM or other malignancies in a dose- and time-dependent manner. Thalidomide-related neuropathy is an asymmetrical, painful,

---

**Figure 67–9** Overview of proposed mechanisms of antitymoma activity of thalidomide and its derivatives. Some biological hallmarks of the malignant phenotype are indicated in blue boxes. The proposed sites of action for thalidomide (letters inside red and green circles) are hypothesized to also be operative for thalidomide derivatives **A.** Direct anti-MM effect on tumor cells, including growth arrest or apoptosis, even against MM cells resistant to conventional therapy. This is due to the disruption of the antiapoptotic effect of BCL2 family members, blocking NF-κB signaling, and inhibition of the production of IL-6. Mechanistic studies show that lenalidomide can kill MM cells by inducing E3 ubiquitin ligase CRL4CRBN-mediated ubiquitination and degradation of the crucial IKZF1 & 3 (zinc finger transcription factors). **B.** Inhibition of MM cell adhesion to bone marrow stromal cells partially due to the reduction of IL-6 release. **C.** Decreased angiogenesis due to the inhibition of cytokine and growth factor production and release. **D.** Enhanced T-cell production of cytokines, such as IL-2 and IFN-γ, that increase the number and cytotoxic functionality of NK cells.

Peripheral paresthesia with sensory loss, commonly presenting with numbness of toes and feet, muscle cramps, weakness, signs of pyramidal tract involvement, and carpal tunnel syndrome. Although symptoms improve on drug discontinuation, long-standing sensory loss may not reverse. Particular caution should be applied in patients with preexisting neuropathy (e.g., related to diabetes) or prior exposure to drugs that can cause peripheral neuropathy (e.g., vinca alkaloids, bortezomib). Thalidomide enhances the sedative effects of barbiturates and alcohol and the catatonic effects of chlorpromazine. Conversely, CNS stimulants (such as methamphetamine and methylenediate) counteract the depressant effects of thalidomide.

Adverse effects of lenalidomide are less severe; it causes little sedation, constipation, or neuropathy. Lenalidomide depresses bone marrow function and is associated with significant leukopenia (20% of patients). Hepatotoxicity and renal dysfunction are rare. In some patients with CLL, lenalidomide causes dramatic lymph node swelling and tumor lysis (tumor flare reaction). Patients with renal dysfunction are prone to this reaction; thus, patients with CLL should be started at lower doses of 10 mg/d, with escalation as tolerated. Patients with CLL should receive pretreatment hydration and allopurinol to avoid the consequences of tumor swelling and tumor lysis. A negative interaction with rituximab, an anti-CD20 antibody, may result from lenalidomide’s downregulation of CD20, an interaction that has clinical implications for their combined use in lymphoid malignancies.
Thalidomide and lenalidomide increase the risk for thromboembolic events, including deep vein thrombosis, stroke, and myocardial infarction, which occur with increased frequency in combination with glucocorticoids and with anthracyclines. Anticoagulation and antiplatelet medication reduce this risk and are indicated in patients with risk factors for clotting.

**Pomalidomide**

Pomalidomide, a thalidomide congener, is indicated for the treatment of patients with MM who have received at least two prior therapies including lenalidomide. Adverse effects are similar to those of thalidomide. Pomalidomide in contraindicated during pregnancy and in females who may become pregnant. As a consequence, this drug is available only under a pregnancy control system to ensure that recipients are not pregnant and are using effective birth control.

**Proteasome Inhibitors**

**First Generation**

**Bortezomib** is a first-generation inhibitor of proteasome-mediated protein degradation that has a central role in the treatment of MM.

**Mechanism of Action**

Bortezomib binds to the β5 subunit of the 20S core of the 26S proteasome and reversibly inhibits its chymotrypsin-like activity. This event disrupts multiple intracellular signaling cascades, leading to apoptosis. An important consequence of proteasome inhibition is its effect on NF-kB, a transcription factor that promotes cell damage response and cell survival. Most cellular NF-kB is cytosolic and bound to IκB; in this form, NF-kB is restricted to the cytosol and cannot enter the nucleus to regulate transcription. In response to stress signals resulting from hypoxia, chemotherapy, and DNA damage, IκB becomes ubiquitinated and then degraded via the proteasome. Its degradation releases NF-kB, which enters the nucleus and transcriptionally activates a host of genes involved in cell survival (e.g., cell adhesion proteins, and proliferation (e.g., cyclin-D1) or antiapoptosis (e.g., cIAPs, BCL-2). NF-kB is highly expressed in many human tumors, including MM, and may be a key factor in tumor cell survival in a hypoxic environment and during chemotherapy. Bortezomib blocks proteasomal degradation of IκB, thereby preventing the transcriptional activity of NF-kB and downregulating survival responses.

Bortezomib also disrupts the ubiquitin-proteasomal degradation of p21, p27, p53, and other key regulators of the cell cycle and initiators of apoptosis. Bortezomib activates the cell’s stereotypical “unfolded protein response,” in which abnormal protein conformation activates adaptive signaling pathways in the cell. The composite effect leads to irreversible commitment of MM cells to apoptosis.

**ADME**

The recommended starting dose of bortezomib is 1.3 mg/m² given as an intravenous bolus on days 1, 4, 8, and 11 of every 21-day cycle (with a 10-day rest period per cycle). At least 72 h should elapse between doses. Drug administration should be withheld until resolution of any grade 3 nonhematological toxicity or grade 4 hematological toxicity, and subsequent doses should be reduced 25%. The drug exhibits a terminal t½ in plasma of 5.5 h. Peak proteasome inhibition reaches 60% within 1 h and declines thereafter, with a t½ of about 24 h. Bortezomib clearance results from the deoroboration of the parent compound (90%), followed by hydroxylation of the boron-free product by CYP3A4 and 2D6; administration of this drug with potent inducers or inhibitors/substrates of CYP3A4 requires caution. No dose adjustment is required for patients with renal dysfunction.

**Therapeutic Uses**

Bortezomib is used as initial therapy for patients with MM and as therapy for patients with MM after relapse from other drugs. It is also approved for treatment of patients with relapsed or refractory MCL. The drug is active in myeloma, including the induction of complete responses in up to 30% of patients when used in combination with other drugs (i.e., thalidomide, lenalidomide, liposomal doxorubicin, or dexamethasone).

**Adverse Effects**

Bortezomib toxicities include thrombocytopenia (28%), fatigue (12%), peripheral neuropathy (12%), neutropenia, anemia, vomiting, diarrhea, limb pain, dehydration, nausea, and weakness. Peripheral neuropathy, the most chronic of the toxicities, develops most frequently in patients with a prior history of neuropathy secondary to prior drug treatment (e.g., thalidomide) or diabetes or with prolonged use. Dose reductions or discontinuation of bortezomib ameliorates the neuropathic symptoms. Injection of bortezomib may precipitate hypotension, especially in volume-depleted patients, in those who have a history of syncope, or in patients taking antihypertensive medications. Cardiac toxicity is rare, but congestive heart failure and prolonged QT interval have been reported.

**Second Generation**

**Carfilzomib** is a second-generation selective proteasome inhibitor based on a tetrapeptide epoxyketone. It is FDA approved as a single agent or in combination with dexamethasone or lenalidomide plus dexamethasone for the treatment of patients with relapsed or refractory MM who have received at least one prior therapy. Frequent adverse effects (>20% of patients) include anemia, thrombocytopenia, diarrhea, dyspnea, and peripheral edema. There is a risk for cardiac, renal, pulmonary, and hepatic toxicity as well as hypertension.

**Ixazomib** is an orally bioavailable second-generation peptide analogue proteasome inhibitor that interacts with subunit beta type 5 (PSMB5) of the 20S proteasome complex. Ixazomib has an elimination half-life of 9.5 days and is approved for use in combination with lenalidomide and dexamethasone for the treatment of patients with MM after at least one prior therapy (Moreau et al., 2016). Ixazomib can cause diarrhea, peripheral neuropathy, and hepatotoxicity.

**Omacetaxine.** This agent’s mechanisms of action include inhibition of protein translation by preventing the initial elongation step of protein synthesis, thereby depleting the cell of short-lived proteins. Omacetaxine is FDA approved for the treatment of patients with chronic or accelerated -phase CML with resistance or intolerance to two or more TKIs.

**CD20 Inhibitors**

CD20 is a cell surface antigen expressed on the surface of all B cells beginning with the pro-B cell stage through its terminal differentiation to plasma cells (see Chapters 34 and 35) and is expressed on about 90% of B-cell neoplasms.

**Rituximab**

Rituximab is a chimeric murine/human monoclonal IgG1 antibody that targets the CD20 B-cell surface antigen. On binding to CD20, rituximab mediates B-cell lysis through CDC and ADCC. In patients with NHL, administration of rituximab depletes circulating and tissue-based B cells within the first 3 weeks, with sustained depletion for 6 to 9 months post-treatment in a majority of patients. Median B-cell levels return to normal by 12 months.

**ADME**

The drug is administered by intravenous infusion both as a single agent and in combination with chemotherapy. Rituximab has a t½ of about 22 days. As a single agent, it is given weekly for 4 weeks, with maintenance dosing every 3–6 months. In combination regimens, the drug may be administered every 3–4 weeks, with chemotherapy, for up to eight doses. The rate of infusion should be increased slowly to prevent serious hypersensitivity reactions. Pretreatment with antihistamines, acetaminophen, and glucocorticoids decreases the risk of hypersensitivity reactions. Patients with large numbers of circulating tumor cells (as in CLL) are at increased risk for tumor lysis syndrome; in these patients, the initial dose should be no more than 50 mg/m² on day 1 of treatment, and patients should receive standard tumor lysis prophylaxis.

**Therapeutic Uses**

Rituximab is approved as a single agent for relapsed indolent lymphomas and significantly enhances response and survival in combination with
Chemotherapy for the initial treatment of diffuse large BCL. Rituximab improves response rates when added to combination chemotherapy for other indolent B-cell NHLs, including CLL, MCL, WM, and marginal zone lymphomas. Maintenance of remission with rituximab delays time to progression and improves overall survival in indolent NHL. It is increasingly used for treatment of autoimmune diseases such as rheumatological disease, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, cryoglobulin-induced renal disease, and multiple sclerosis.

**Resistance and Adverse Effects**

Resistance to rituximab may emerge through downregulation of CD20, impaired antibody-dependent cellular cytotoxicity, decreased complement activation, limited effects on signaling and induction of apoptosis, and inadequate blood levels. Polymorphisms in two of the receptors for the antibody Fc region responsible for complement activation may predict the clinical response to rituximab monotherapy in patients with follicular lymphoma but not in CLL. Rituximab infusion reactions can be life-threatening, but with pretreatment, reactions are usually mild and limited to fever, chills, throat itching, urticaria, and mild hypotension. All respond to decreased infusion rates and antihistamines. Uncommonly, patients may develop severe mucocutaneous skin reactions, including Stevens-Johnson syndrome. Rituximab may cause reactivation of hepatitis B virus or rarely, JC virus (with progressive multifocal leukoencephalopathy). Hypogammaglobulinemia and autoimmune syndromes (idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, autoimmune hemolytic anemia, pure red cell aplasia, and delayed neutropenia) may supervene 1–5 months after administration.

**Ofatumumab**

Ofatumumab is a second monoclonal antibody that binds to CD20 at sites on the major and minor extracellular loops of CD20, distinct from the site targeted by rituximab. Antibody binding results in B-cell lysis via CDC and ADCC. Ofatumumab is approved for treating patients with CLL after failure of fludarabine and alemtuzumab. A complex dosing scheme is used, beginning with small (300-mg) doses on day 1, followed by higher doses (up to 2 g/week) later. Ofatumumab’s primary toxicities consist of immunosuppression and opportunistic infection, hypersensitivity reactions during antibody infusion, and myelosuppression. Blood counts should be monitored during treatment. Rarely, patients may develop reactivation of viral infections. The drug should not be administered to patients with active hepatitis B infection; liver function should be monitored in hepatitis B carriers.

**Obinutuzumab**

Obinutuzumab is a humanized monoclonal IgG1 antibody that recognizes the CD20 antigen expressed on the surface of B cells. On binding to CD20, obinutuzumab mediates B-cell lysis through CDC and ADCC. Obinutuzumab is approved for the treatment of treatment-naive patients with CLL in combination with chemotherapy. Patients who receive this combination therapy are more likely to go into complete remission and have better overall survival than those receiving chlorambucil alone. In this study, they also compared patients treated with obinutuzumab and chlorambucil to patients who were treated with rituximab and chlorambucil. A comparison of patients with CLL given obinutuzumab-chlorambucil combination therapy versus rituximab-chlorambucil combination therapy showed that the obinutuzumab-chlorambucil combination provided higher rates of complete remission as well as longer progression-free survival. Cytopenias, fever, cough, and musculoskeletal disorders are frequent side effects.

**Other Cell Surface Targets for Monoclonal Antibodies**

**Alemtuzumab**

Alemtuzumab is a humanized IgG-κ monoclonal antibody that binds to CD52 antigen. CD52 is found on the surface of a subset of normal neutrophils and on all B and T lymphocytes, on testicular elements and sperm, and on most BCLs and T-cell lymphomas. Consistently high levels of CD52 expression on lymphoid tumor cells and the lack of CD52 modulation with antibody binding make this antigen a potential target for unconjugated monoclonal antibodies. Alemtuzumab can induce tumor cell death through ADCC and CDC.

**ADME**

Alemtuzumab is administered intravenously in dosages of 30 mg/d. three times/week. Premedication with diphenhydramine and acetaminophen should precede drug infusion. Dosing should begin with a low-dose infusion, followed by an increased dose 2 days later and, if well tolerated, the highest dose 2 days later. The drug has an initial mean t½ of 1 h, but after multiple doses, the t½ extends to 12 days, and steady-state plasma levels are reached at approximately week 6 of treatment.

**Therapeutic Uses**

Alemtuzumab is approved as a single agent for the treatment of B-cell CLL. Clinical activity had been demonstrated in both B- and T-cell low-grade lymphomas and CLL, including patients with disease refractory to purine analogues. In chemotherapy-refractory CLL, overall response rates are about 40%, with complete responses of 6% in multiple series. Response rates in treatment-naive patients with CLL are higher (overall response rates of 83% and complete responses of 24%). Alemtuzumab is also approved for the treatment of patients with relapsing forms of multiple sclerosis under a different label.

**Adverse Effects**

Serious toxicities include acute infusion reactions and depletion of normal neutrophils and T cells. Myelosuppression, with depletion of all blood lineages, occurs in the majority of patients and may represent either direct marrow toxicity or autoimmune responses. Immunosuppression leads to a significant risk of fungal, viral, and other opportunistic infections, particularly in patients who have previously received purine analogues. Patients should receive prophylaxis against *Pneumocystis carinii* and herpesvirus during treatment and for at least 2 months following therapy with alemtuzumab. Because reactivation of cytomegalovirus (CMV) infections may follow antibody use, patients should be monitored for symptoms and signs of viremia, hepatitis, and pneumonia. CD4+ T-cell counts may remain profoundly depleted (<200 cells/µL) for 1 year.

**Dinutuximab**

Dinutuximab is a monoclonal antibody that targets glycolipid GD2, expressed on neuroblastoma cells and on normal cells of neuroectodermal origin, including the CNS and peripheral nerves. It is approved in combination with GM-CSF, IL-2, and RA for high-risk neuroblastoma in pediatric patients. Dinutuximab can cause nerve damage and life-threatening infusion reactions.

**Daratumumab**

Daratumumab is a human IgG1 monoclonal antibody that binds to CD38 and inhibits the growth of CD38-expressing tumor cells by inducing immune-mediated tumor cell lysis through CDC and ADCC. The FDA has recently approved daratumumab for treatment of patients with MM in combination with lenalidomide or bortezomib and dexamethasone. The most frequent adverse effects are infusion reactions, neutropenia, thrombocytopenia, fatigue, nausea, diarrhea, muscle spasms, back pain, pyrexia, cough, dyspnea, peripheral edema, peripheral sensory neuropathy, and upper respiratory tract infection.

**Elotuzumab**

Elotuzumab is a humanized monoclonal IgG antibody that targets SLAMF7 (CD319). It is approved for the treatment of patients with MM who have received one to three prior therapies. Binding of elotuzumab to the antigen on myeloma cells induces ADCC-dependent tumor cell lysis. ADCC is enhanced by stimulation of the SLAMF7 pathway in NK cells by elotuzumab.
Blinatumomab
Blinatumomab is a bispecific antibody that recognizes sites on the surfaces of B cells and T cells, thereby enabling a patient’s T cells to recognize malignant B cells. Blinatumomab binds simultaneously to CD3 (part of the TCR) on T cells and to CD19 on B cells. The drug links these two cell types and activates the T cell to exert cytotoxic activity on CD19+ target B cells. Blinatumomab is approved for the Philadelphia chromosome-negative relapsed or refractory B-cell precursor ALL. Major adverse effects are cytokine release syndrome, neurologic toxicities, neutropenic fever, and sepsis.

Monoclonal Antibody–Cytotoxin Conjugates

Gemtuzumab Ozogamicin

Mechanism of Action
Gemtuzumab ozogamicin is a humanized monoclonal antibody against CD33 covalently linked to a semisynthetic derivative of calicheamicin, a potent antitumor antibiotic. The CD33 antigen is present on most hematopoietic cells, on more than 80% of AMLs, and on most myeloid cells in patients with MDSs. However, other normal cell types lack CD33 expression, making this antigen attractive for targeted therapy. CD33 has no known biological function, although monoclonal antibody cross-linking inhibits normal and myeloid leukemia cell proliferation. Following its binding to CD33, gemtuzumab ozogamicin undergoes endocytosis; cleavage of calicheamicin from the antibody takes place within the lysosome. The potent toxin then enters the nucleus, binds in the minor groove of DNA, and causes double-strand DNA breaks and cell death.

ADME
The antibody conjugate produces a 30% complete response rate in relapsed AML when administered at a dose of 9 mg/m^2 for up to three doses at 2-week intervals. The t_1/2 of total and unconjugated calicheamicin are 41 and 143 h, respectively. Following a second dose, the t_1/2 of drug-antibody conjugate increases to 64 h. Most patients require two to three doses to achieve remission.

Therapeutic Use
The drug was initially approved for use in patients more than 60 years of age with AML in first relapse. However, the drug is not yet available, pending clinical trials to more precisely define a population with high likelihood of efficacy. Primary toxicities include myelosuppression in all patients treated and hepatocellular damage in 30%–40% of patients, manifested by hyperbilirubinemia and enzyme elevations. This agent also causes a syndrome that resembles hepatic veno-occlusive disease when patients subsequently undergo myeloablative therapy or when gemtuzumab ozogamicin follows high-dose chemotherapy.

Brentuximab Vedotin
Brentuximab vedotin is an anti-CD30 IgG1 monoclonal antibody linked with the microtubule-disrupting agent MMAE. CD30 is expressed on more than 80% of Hodgkin and anaplastic lymphoma. Binding of the antibody to CD30-expressing cells is followed by internalization and the intracellular release of MMAE via proteolytic cleavage. MMAE disrupts the microtubule network, inducing cell cycle arrest and apoptotic cell death. MMAE is mostly metabolized by CYP3A, and coadministration with CYP3A4 inhibitors will increase exposure to the MMAE toxin. Coadministration with CYP3A4 inducers (e.g., rifampin) reduces exposure. The most common adverse reactions are neutropenia, peripheral sensory neuropathy, fatigue, nausea, anemia, upper respiratory tract infection, diarrhea, pyrexia, rash, thrombocytopenia, cough, and vomiting.

Ado-trastuzumab Emtansine
Ado-trastuzumab-DM1 combines the HER2-targeted properties of trastuzumab with the antimitotubule agent DM1 (derived from maytansine), allowing preferential intracellular drug delivery to HER2+ cells in the treatment of HER2+ breast cancer. The complex binds to the EGFR2 (HER2) and enters the cell by receptor-mediated endocytosis. The DM1 (emtansine) is released into the cytosol as the complex is cleaved by proteases in lysosomes. The DM1 disrupts microtubule-dependent events, causing mitotic arrest, disruption of intracellular trafficking, and apoptosis. The adverse effects of treatment include cardiac dysfunction as described for unconjugated trastuzumab. Hepatotoxicity is an additional risk.

Denileukin Diftitox
Denileukin diftitox is an immunotoxin made from the genetic recombination of IL-2 and the catalytically active fragment of diphtheria toxin. The high-affinity IL-2R has limited tissue expression and is an attractive target for an immunotoxin. Introduction of the diphtheria toxin fragment into cells leads to ADP-ribosylation and inactivation of eukaryotic elongation factor EF-2, inhibition of protein synthesis, and thence cell death.

ADME
Denileukin diftitox is administered by intravenous infusion over 30–60 min for 5 consecutive days every 21 days for eight cycles. The drug is quickly distributed and has a terminal t_1/2 of about 70 min. Denileukin diftitox clearance in later cycles of treatment accelerates by 2- to 3-fold as a result of development of antibodies, but serum levels exceed those required to produce cell death in IL-2R-expressing cell lines (1–10 ng/mL for > 90 min).

Therapeutic Uses
Denileukin diftitox is approved for the treatment of recurrent/refractory cutaneous T-cell lymphomas. Response rates of 30%–37% have been achieved, with a median response duration of 6.9 months. Patients with a history of hypersensitivity reactions to diphtheria toxin or IL-2 should not be treated. Significant toxicities include acute hypersensitivity reactions, a vascular leak syndrome, and constitutional toxicities; glucocorticoid premedication significantly decreases toxicity.

Radioimmunoconjugates
Radioimmunoconjugates provide targeted delivery of radionuclides to tumor cells. I131Iodine (I131I) is a favored radioisotope because it is readily available, relatively inexpensive, and easily conjugated to a monoclonal antibody. The β particles emitted by 131I can be used for both imaging and therapy, but protein-Iodine conjugates have the drawback of releasing free 131I and 131I-tyrosine into the blood and thus present a health hazard to people in contact with the patient. The β-emitter 90Y (yttrium) has emerged as an alternative to 131I based on its higher energy and longer path length. Thus, it may be more effective in tumors with larger diameters. It also has a short t_1/2 and remains conjugated, even after endocytosis, providing a safer profile for outpatient use. Currently available radioimmunoconjugates consist of murine monoclonal antibodies against CD20 conjugated with 131I (tositumomab) or 90Y (britunomab). Both drugs have shown responses rates in relapsed lymphoma of 65%–80%. Adverse effects include antibody-related hypersensitivity, bone marrow suppression, and secondary leukemias. Both radioimmunoconjugates targeting CD20 on lymphomas have been approved; concerns over toxicity have limited their use.

Cytokines and Growth Factors

Colony-Stimulating Factors
Many agents used for cancer chemotherapy suppress the production of multiple types of hematopoietic cells, and bone marrow suppression can limit the delivery of chemotherapy on schedule and at prescribed doses. The availability of recombinant growth factors for erythrocytes (i.e., erythropoietin), granulocytes (i.e., G-CSF), and granulocytes and macrophages (i.e., GM-CSF) has advanced the ability to use combination therapy or high-dose cytotoxic therapy with diminished complications such as febrile neutropenia (see Chapter 66). Chapter 41 presents the basic pharmacology of hematopoietic growth factors.
**Inhibitors of Histone Deacetylase**

Histone deacetylases are a class of enzymes that catalyze the removal of acetyl groups from acetylated lysine amino acids in histones, thereby altering the transcriptional activation of cellular genes. Thus, HDAC inhibitors produce a broad spectrum of epigenetic effects. HDACs can also deacetylate other proteins, including transcription factors. Overexpression of HDACs found in some cancers, or aberrant recruitment of HDACs to oncogenic transcription factors, can cause hypoacetylation of core nucleosomal histones. This hypoacetylation results in the condensation of chromatin structure and repression of gene transcription. In contrast, inhibition of HDAC activity leads to the accumulation of acetyl groups on the histone lysine residues, an open chromatin structure, and activation of target genes that are selectively repressed in tumors. The result of HDAC inhibition can be differentiation with the emergence of a more normal cellular phenotype or cell cycle arrest with expression of endogenous regulators of cell cycle progression. Due to the diversity of the HDAC family of enzymes and their tissue distribution, HDAC inhibitors with different selectivity can induce a wide variety of cellular effects.

**Panobinostat**

Panobinostat is an orally bioavailable, nonselective pan-HDAC inhibitor. The inhibitory activity leads to apoptosis of malignant cells via multiple pathways. Panobinostat is approved for the treatment of patients with MM who have received at least two previous treatments, including bortezomib and an immunomodulatory agent.

**ADME**

The oral bioavailability is about 21%. Panobinostat is metabolized through CYP3A. It is recommended to avoid concomitant use with strong CYP3A4 inducers or inhibitors. Otherwise, dose adjustments will be necessary. The elimination half-life is approximately 37 h.

**Adverse Effects**

The most common adverse effects are diarrhea (severe in 25% of patients), fatigue, nausea, peripheral edema, decreased appetite, pyrexia, and vomiting. The most common nonhematologic laboratory abnormalities (incidence ≥ 40%) are hypophosphatemia, hypokalemia, hyponatremia, and increased creatinine. The common hematologic laboratory abnormalities (incidence ≥ 60%) are thrombocytopenia, lymphopenia, leukopenia, neutropenia, and anemia. Fatal cardiac ischemic events, severe arrhythmias, and ECG changes have occurred in patients receiving panobinostat. Arrhythmias may be exacerbated by electrolyte abnormalities. Avoid concomitant use of antiarrhythmic or QT-prolonging drugs. Close cardiac monitoring during treatment is recommended.

**Romidepsin**

Romidepsin is an HDAC inhibitor used in the treatment of cutaneous and peripheral T-cell lymphoma. Romidepsin is a natural product obtained from the bacteria *Chromobacterium violaceum* and is sometimes referred to as depsipeptide. Romidepsin functions as a prodrug. Within cells, a zinc-binding thiol of the drug is reduced and interacts with a zinc atom in the binding pocket of HDAC to block its activity.

**ADME**

After intravenous administration, the major metabolism is through CYP3A4. Thus, it is recommended to monitor for toxicities related to increased romidepsin exposure when coadministering strong CYP3A4 inhibitors. Avoid use with rifampin and other strong CYP3A4 inducers. The terminal half-life is about 3 h.

**Adverse Effects**

The most commonly observed are nausea and vomiting, anemia, thrombocytopenia, and leukopenia as well as abnormal electrolyte levels and ECG changes.

**Vorinostat**

Vorinostat is a small-molecule, orally bioavailable HDAC inhibitor; it is also known as SAHA based on its chemical name suberanilhydroxamic acid.

**Mechanism of Action**

Vorinostat binds to the active site of HDACs and chelates zinc ions in the active site. The inhibition of HDACs causes the accumulation of acetylated histones and other acetylated proteins, amongst which are transcription factors crucial for cell differentiation. Vorinostat inhibits the enzymatic activities of HDAC1, 2, 3 (class I) and HDAC6 (class II) at nanomolar concentrations (IC₅₀ < 100 nM). In vitro, vorinostat induces cell cycle arrest or apoptosis of some cancer cells.

**ADME**

The absorption of vorinostat is slightly improved when taken with a meal. Metabolism is mostly through glucuronidation and hydrolysis. The elimination t½ is about 2 h.

**Therapeutic Use; Adverse Effects**

Vorinostat is approved for the treatment of patients with cutaneous T-cell lymphoma with persistent or recurrent disease after two systemic therapies. The most common adverse reactions are diarrhea, fatigue, nausea, thrombocytopenia, anorexia, and dysgeusia. Patients with severe hepatic impairment should be excluded from treatment. Vorinostat is classified as pregnancy category D: evidence of risk.

### mTOR (Mechanistic or Mammalian Target of Rapamycin) Inhibitors

<table>
<thead>
<tr>
<th>Inhibitor</th>
<th>Indications</th>
<th>Adverse Effects</th>
</tr>
</thead>
</table>
| Temsirolimus | Renal cell carcinoma | • Adverse effects: frequent rash, mucositis, anemia, fatigue (30%–50%); rare leukopenia, thrombocytopenia, interstitial lung disease  
• Metabolized to a longer-lived active metabolite (sirolimus) by CYP3A4: avoid CYP3A4 inhibitors, including grapefruit juice |
| Everolimus | Renal cell carcinoma  
Breast cancer: advanced ER positive, HER2 negative in combination with AI exemestane after failure of other AIs (letrozole, anastrazole)  
PNETs  
Progressive, well-differentiated, nonfunctional neuroendocrine GIST | • Adverse effects overlap with temsirolimus (see above)  
• CYP3A4 substrate |

### Multikinase Inhibitors

<table>
<thead>
<tr>
<th>Inhibitor</th>
<th>Indications</th>
<th>Adverse Effects</th>
</tr>
</thead>
</table>
| Cabozantinib | Advanced renal cell carcinoma  
Lung adenocarcinoma with MET gene alteration | • Diarrhea, fatigue, nausea, abdominal pain  
• Hypertension: monitor blood pressure  
• Not indicated in patients with recent bleeding history or thromboembolic event  
• Discontinue in patients with GI perforation, fistulas  
• CYP3A4 substrate; ↓ dose with hepatic impairment |
| Vandetanib | Progressing, locally advanced medullary thyroid cancer | • Diarrhea, colitis, rash  
• QT interval prolongation, torsades des pointes, sudden death  
• Do not use in patients with hepatic impairment, long QT syndrome  
• CYP3A4 substrate |

### Section III: Inhibitors of Tumor Angiogenesis

#### Vascular Endothelial Growth Factor Inhibitors

<table>
<thead>
<tr>
<th>Inhibitor</th>
<th>Indications</th>
<th>Adverse Effects</th>
</tr>
</thead>
</table>
| Bevacizumab (humanized IgG1) | Metastatic colorectal cancer combined with chemotherapy (FOLFOX or FOLFIRI)  
NSCLC combined with carboplatin and paclitaxel  
Ovarian cancer combined with chemotherapy  
Renal cell carcinoma combined with interferon α  
Glioblastoma following prior therapy | • Hypertension, related congestive heart failure: monitor blood pressure and treat hypertension  
• Impaired wound healing: delay elective surgery for 1 month after the last dose; do not resume treatment for at least 1 month after surgery  
• Spontaneous GI perforation |
| Ramucirumab (fully human IgG1 to VEGFR2) | Metastatic colorectal cancer, advanced gastric adenocarcinoma, and NSCLC with disease progression on or after prior therapy as a single drug or in combination with chemotherapy | • Hypertension, diarrhea  
• Hemorrhage, GI perforations  
• Impaired wound healing |
| Aflibercept (extracellular domain of VEGFR1/2 fused to Fc portion of human IgG1) | Metastatic colorectal cancer in combination with FOLFIRI chemotherapy following FOLFOX | • Soluble trap for VEGF receptor ligands  
• Hypertension, diarrhea  
• Increased risk of hemorrhage, GI perforation  
• Impaired wound healing |

#### Inhibitors of Intracellular Kinases Participating in Angiogenesis

<table>
<thead>
<tr>
<th>Inhibitor</th>
<th>Indications</th>
<th>Adverse Effects</th>
</tr>
</thead>
</table>
| Sunitinib | VEGFR2 and multiple other kinases inhibited  
GIST after imatinib resistance  
Pancreatic neuroendocrine tumors | • Adverse effects shared with anti-VEGF: bleeding, hypertension, proteinuria (frequent); thromboembolism, GI perforations (rare)  
• Adverse events distinct from anti-VEGF:  
  • Fatigue (50%–70%), hypothyroidism (40%–60%)  
  • Common: bone marrow suppression and diarrhea  
  • Less common: hepatotoxicity, congestive heart failure  
  • Check blood pressure, blood counts, and thyroid functions at regular intervals  
  • Elimination t1/2 ~ 4 days: regimen in some cancers is 4 weeks on, 2 weeks off versus continuous daily administration for other cancers |
| Sorafenib | Hepatocellular carcinoma (currently the only approved drug)  
Metastatic renal cell cancer (however, sunitinib is the first choice) | • Adverse vascular effects match with those of sunitinib  
• More common: fatigue, diarrhea, anorexia, rash  
• Less common: bone marrow suppression, GI perforation, cardiomyopathy |
| Axitinib | Inhibition of VEGFR1–3  
Advanced renal cell cancer after failure of prior systemic therapy | • Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation  
• CYP3A4/5 substrate |
| Lenvatinib | Inhibition of VEGFR1–3, FGFRs, PDGFR  
Recurrent or metastatic differentiated thyroid cancer  
Renal cell cancer in combination with everolimus | • Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation  
• In addition: hepatotoxicity, QT prolongation  
• CYP3A substrate |
### Pathway-Targeted Therapies

**Chapter 67**

#### Pazopanib
- Inhibition of VEGFR1–3, FGFRs, KIT, PDGFR
- Advanced renal cell carcinoma and advanced soft-tissue sarcoma after prior chemotherapy
- Adverse effects overlap with those of anti-VEGF: hypertension, thrombotic and hemorrhagic events, GI perforation
- In addition: hepatotoxicity, QT prolongation
- CYP3A substrate

#### Regorafenib
- Inhibition of RET, VEGFR1, PDGFR, FGFR, TIE2, RAF1, BRAF, ABL
- Metastatic colorectal cancer after previous chemotherapy and anti-VEGF or anti-EGFR
- Advanced GIST after imatinib or sunitinib
- Major adverse effects: hepatotoxicity, hypertension, thrombotic and hemorrhagic events, GI perforation, and wound-healing complications
- CYP3A substrate

### Section IV: Drugs Targeting the Immune System

#### Immune Checkpoint Inhibitors

**Ipilimumab** (anti-CTLA-4 fully human IgG1)
- Metastatic melanoma as single agent or in combination with nivolumab (anti-PD1)
- Clinical trials with different cancers are ongoing
- Autoimmunity inflammatory toxicities in majority of patients (>70%)
- Most frequent: skin (pruritus, rash, vitiligo), GI tract (diarrhea, colitis)
- Less frequent: hepatitis, pneumonitis, hypophysitis, hypophysitis, hypo- or hyperthyroidism, mycarditis

** Tremelimumab** (anti-CTLA-4 fully human IgG2)
- Clinical trials with different cancers are ongoing
- See above

**Nivolumab** (anti-PD-1 fully human IgG4)
- Advanced melanoma that progressed after ipilimumab (anti–CTLA-4)
- Previously treated NSCLC
- Advanced renal cell carcinoma
- Relapsed/refractory Hodgkin lymphoma
- Adverse effects: rash, fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, constipation
- Immune-related serious adverse effects include pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypophysitis, hypo- and hyperthyroidism

**Pembrolizumab** (anti-PD-1 humanized IgG4)
- Advanced melanoma that progressed after ipilimumab (anti–CTLA-4)
- NSCLC that express PD-L1 and progressed under chemotherapy
- NSCLC with wild-type EGFR and ALK and disease progression after chemotherapy
- HNSCC with disease progression after chemotherapy
- Adverse effects: rash, fatigue, dyspnea, musculoskeletal pain, decreased appetite, cough, nausea, constipation
- Immune-related serious adverse effects include pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypophysitis, hypo- and hyperthyroidism

**Atezolizumab** (anti-PD-L1 fully human IgG1)
- NSCLC that is treatment resistant
- Urothelial cancer that is locally advanced or metastatic
- Adverse effects: fatigue, decreased appetite, dyspnea, cough, nausea, musculoskeletal pain, constipation
- In patients with urothelial cancer: urinary tract infections
- Immune-related pneumonitis, colitis, hepatitis, nephritis, renal dysfunction, hypo- and hyperthyroidism, hypophysitis, adrenal insufficiency, pancreatitis, Guillain-Barre syndrome, severe infections

### Section V: Inhibitors of Other Targets

#### Poly(ADP-Ribose) Polymerase Inhibitor

**Olaparib** PARP (poly(ADP-ribose) polymerase) inhibitor
- Ovarian cancer after three or more prior lines of treatment in patients with germ line mutant BRCA
- Adverse effects: nausea, vomiting, loss of appetite, muscle and joint pain, anemia; leukemia (rare), potentially fatal myelodysplastic (rare) syndrome pneumonitis
- CYP3A4 substrate

#### BCL2 (Antiapoptotic Protein): Orally Available Inhibitor

**Venetoclax**
- CLL with 17p deletion (poor prognosis)
- Neutropenia; thrombocytopenia, diarrhea, nausea
- Absorption ↑ 3- to 5-fold with a meal
- CYP3A substrate

#### Thalidomide and Lenalidomide

**Thalidomide**
- Newly diagnosed multiple myeloma
- Relapsed or refractory, pretreated multiple myeloma
- Most serious adverse effect: sensory neuropathy in 10%–30% of patients; may not be reversible after discontinuation of treatment; patients with preexisting neuropathy at higher risk
- Teratogenic; do not use in pregnancy
- Causes sedation, fatigue, constipation
- Sedation enhanced by alcohol, chlorpromazine, barbiturates; counteracted by methylphenidate or methamphetamine

**Lenalidomide**
- Newly diagnosed multiple myeloma
- Relapsed or refractory, pretreated multiple myeloma
- Most serious adverse effect: sensory neuropathy in 10%–30% of patients; may not be reversible after discontinuation of treatment; patients with preexisting neuropathy at higher risk
- Teratogenic; do not use in pregnancy
- Causes sedation, fatigue, constipation
- Sedation enhanced by alcohol, chlorpromazine, barbiturates; counteracted by methylphenidate or methamphetamine

Note: CYP3A4 substrate. For drugs that are subject to hepatic metabolism by CYP enzymes, drug exposure of a patient can be affected by coadministration of inhibitors or inducers of CYP3A4 and can then reduce efficacy or increase side effects.

Embryo-fetal toxicity: Consider that all of these drugs can cause fetal harm. Advise women of the potential risk to a fetus and to avoid pregnancy while taking the drug and for 1 month after cessation of therapy. Advise men to avoid fathering a child during the same time period. Avoid lactation during therapies.

### Bibliography

Hormones and Related Agents in the Therapy of Cancer
Claudine Isaacs, Anton Wellstein, and Anna T. Riegel

DRUGS THAT TARGET THE GLUCOCORTICOID RECEPTOR

ESTROGENS AND ANDROGENS IN CANCER
- Hormone Therapy of Breast Cancer
- Hormone Therapy of Prostate Cancer

A Note on Treatment Regimens
Cancer treatment regimens change to reflect continuous advances in basic and clinical science: new drugs, both small molecules and biologics; improved methods of targeting and timing of drug delivery; agents with altered pharmacokinetic properties and selectivities; the use of rational multidrug combinations; and greater knowledge of the basic cell biology of tumorigenesis, metastasis, and immune function, amongst other advances. As a consequence, this chapter presents relatively few detailed treatment regimens; rather, we refer the reader to the web-based resources of the U.S. FDA and the NCCN. Table 67–1 provides the details and demonstrates the complexities of treatment of two cancers.

The growth of a number of cancers is hormone dependent or regulated by hormones. Glucocorticoids are used for their antiproliferative and lympholytic properties and to ameliorate untoward responses to other treatments. Estrogen and androgen antagonists, steroid synthesis inhibitors, and GnRH analogues and antagonists are all effective in extending survival and delaying or preventing tumor recurrence of both breast and prostate cancer. These molecules interrupt the stimulatory axis created by systemic pools of androgens and estrogens, inhibit hormone production or hormone binding to receptors, and ultimately block expression of genes that promote tumor growth and survival.

Drugs That Target the Glucocorticoid Receptor

The pharmacology, major therapeutic uses, and toxic effects of the glucocorticoids are discussed in Chapter 46. Only the applications of these drugs in the treatment of neoplastic disease are considered here.

Glucocorticoids act by binding to a specific GR that is a member of the nuclear receptor family of transcription factors. The GR translocates to the nucleus and induces complex gene expression changes (Chapter 46) that lead to antiproliferative and apoptotic responses in sensitive cells. Because of their lympholytic effects and their ability to suppress mitosis in hematological tumors, glucocorticoids are used as cytotoxic agents in the treatment of acute leukemia in children and malignant lymphoma in children and adults. In acute lymphoblastic or undifferentiated leukemia of childhood, glucocorticoids may produce prompt clinical improvement and objective hematological remissions in 30% of children. However, the duration of remission is brief. Remissions occur more rapidly with glucocorticoids than with antimetabolites, and there is no evidence of cross-resistance to unrelated agents. Thus, therapy is initiated with prednisone and vincristine, often followed by an anthracycline or methotrexate, and L-asparaginase. Glucocorticoids are a valuable component of curative regimens for other lymphoid malignancies, including Hodgkin disease, non-Hodgkin lymphoma, multiple myeloma, and CLL. Glucocorticoids are extremely helpful in controlling autoimmune hemolytic anemia and thrombocytopenia associated with CLL.

A number of glucocorticoids are available and at equivalent dosages exert similar effects (see Chapter 46). Prednisone, for example, usually is administered orally in doses up to 100 mg for the first few days and gradually reduced to the lowest possible effective dose. Side effects of these agents include glucose intolerance, immunosuppression, osteoporosis, and psychosis (see Chapter 46). Dexamethasone is one of the preferred agents for remission induction in multiple myeloma, typically in combination with bortezomib, anthracyclines, or lenalidomide. Glucocorticoids, particularly dexamethasone, are used in conjunction with radiotherapy to reduce edema related to tumors in critical areas such as the superior mediastinum, brain, and spinal cord. Frequent lower doses (4–6 mg every 6 h) can have dramatic effects in restoring neurological function in patients with cerebral metastases, but these effects are temporary. However, acute changes in dexamethasone dosage can lead to a rapid recrudescence of symptoms. Dexamethasone should not be discontinued abruptly in patients receiving radiotherapy or chemotherapy for brain metastases. Dexamethasone is also frequently used as part of an antiemetic regimen in patients receiving chemotherapy.

Estrogens and Androgens in Cancer

The pharmacology of the estrogens and androgens is described in detail in Chapters 44 and 45. These agents are of value in certain cancers, most notably those of the prostate and breast, because these organs are dependent on hormones for their growth, function, and morphological integrity.

Hormone Therapy of Breast Cancer

Historically, high doses of estrogen have been recognized as effective treatment of breast cancer. More recent studies have suggested lower doses of estrogen can be effective in the management of endocrine-resistant disease (Ellis et al., 2009). The growth inhibitory effect of estrogens may be related to their ability to induce apoptosis in endocrine-resistant breast cancer (Jordan, 2015; Song and Santen, 2003). However, interruption of estrogen-induced signaling with antiestrogens such as tamoxifen and drugs that reduce estrogen production such as AIs and GnRH analogues have been found to be more effective and better tolerated. These drugs have largely replaced estrogens or androgens for the treatment of breast cancer.

The presence of the ER and PR in breast cancer tissue identifies the subset of hormone-receptor-positive (HR+) patients with a more than 60% likelihood of responding to hormonal therapy. The response rate to antiestrogen treatment is somewhat lower in the subset of patients with tumors that are ER+ or PR+ but also positive for human epidermal growth factor receptor HER2/neu amplification. In contrast, ER-negative and
Tamoxifen is given orally once per day. Tamoxifen and other selective estrogen receptor modulators (SERMs) such as raloxifene are also used for the prevention of breast cancer in high-risk patients such as those with a strong family history or prior nonmalignant breast pathology (Visvanathan et al., 2013). The uses, pharmacology, and mechanism of action of raloxifene are discussed in Chapter 44.

- **Mechanism of Action.** Tamoxifen is a competitive inhibitor of estrogens (e.g., 17β-estradiol), binding to the ER, and antagonizes estrogen-induced proliferation of human breast cancer. There are two subtypes of ERs: ERα and ERβ, which have different tissue distributions and can either homo- or heterodimerize. Binding of estrogen and SERMs to the estrogen-binding sites of the ERs initiates a change in conformation of the ER, dissociation of the ER from heat-shock proteins, and ER dimerization. Dimerization facilitates the binding of the ER to specific DNA EREs in the vicinity of estrogen-regulated genes. Coregulator proteins interact with the liganded receptor to act as corepressors or coactivators of gene expression (Chapter 44). Elegant studies of the crystal structure of ERα bound to different ligands indicate that, when an ER agonist is bound to the ligand-binding domain of the ER, helix 12 enables recruitment of coactivators. Conversely, with an estrogen antagonist such as 4-hydroxytamoxifen bound to the ER, helix 12 is displaced, the binding of coactivators is disrupted, and subsequent estrogen-induced gene transcription is inhibited (Nettles and Greene, 2005). Differences in tissue distribution of the ER subtypes and the function and relative amounts of different transcriptional coregulator proteins likely explain the antagonist response to tamoxifen in ERα breast cancer and partial agonist activities in noncancerous tissues. Organs displaying agonist effects of tamoxifen include the uterus (endometrial hyperplasia, vaginal bleeding, and endometrial cancer); the coagulation system (thromboembolism); bone metabolism (increase in bone mineral density, which can slow development of osteoporosis); and liver (tamoxifen lowers total serum cholesterol, low-density lipoprotein cholesterol, and lipoproteins and raises apolipoprotein A-1 levels).

- **ADME.** Tamoxifen is readily absorbed following oral administration, with peak concentrations measurable after 3–7 h and steady-state levels reached at 4–6 weeks. Metabolism of tamoxifen is complex and principally involves CYPs 3A4/5, and 2D6 in the formation of N-desmethyl tamoxifen and CYP2D6 to form 4-hydroxytamoxifen, a more potent metabolite (Figure 68–1). Both metabolites can be further converted to 4-hydroxy-N-desmethyltamoxifen (endoxifen), which retains high affinity for the ER. The parent drug has a terminal 1/2 of 7 days after enterohepatic circulation, glucuronides and other metabolites are excreted in the stool; excretion in the urine is minimal. Polymorphisms in CYP2D6 that reduce its activity lead to lower plasma levels of the potent metabolites 4-OH tamoxifen and endoxifen, but whether this leads to inferior efficacy of tamoxifen treatment and higher risks of disease relapse is unclear (Hertz and Rae, 2016). While drugs that inhibit CYP2D6 activity, such as antidepressants, have been postulated to minimize tamoxifen activity in breast cancer, more recent studies do not suggest a clinically significant impact (Haque et al., 2016).

- **Therapeutic Uses.** Tamoxifen is given orally once per day. Tamoxifen is used for the treatment of women with ER+ metastatic breast cancer or following primary excision of an ER+ tumor as an adjuvant treatment to prevent recurrence and extend overall survival. For the adjuvant treatment of premenopausal women, tamoxifen is given for at least 5 years (Table 68–1). Tamoxifen may also be used for postmenopausal women, but AIs are preferred as they are associated with further reductions in the risk of recurrence (Early Breast Cancer Trialists’ Collaborative Group, 2015). Recent studies indicated that patients with breast cancer derive modest additional benefit, in terms of disease-free survival, overall survival, and decrease in contralateral breast cancer risk, if tamoxifen is taken for up to 10 years or AIs are continued for 5–10 years after completion of 5 years of tamoxifen (Davies et al., 2013; Goss et al., 2016). Of note, while taken for a finite time, Tamoxifen has been shown to have persisting long-term benefits (Ekhholm et al., 2016). Tamoxifen may be taken as sole adjuvant therapy or after adjuvant chemotherapy (Table 68–1). Alternative or additional antiestrogen strategies in the adjuvant treatment of premenopausal women with ER+ breast cancer include oophorectomy or

PR-negative carcinomas do not respond to hormonal therapy. In patients with metastatic cancer, responses to hormonal therapy may not be apparent clinically or by imaging for 8–12 weeks. The medication typically should be continued until the disease progresses or unwanted toxicities develop.

Antiestrogen approaches for the therapy of HR+ breast cancer include the use of SERMs, SERDs, and AIs (Table 68–1).

**Drugs That Target the Estrogen Receptor**

**Selective Estrogen Receptor Modulators.** The SERMs bind to the ER and exert either estrogenic or antiestrogenic effects, depending on the specific organ (Chapter 44). Tamoxifen is the most widely studied antiestrogenic drug used in the treatment of breast cancer. Tamoxifen also exerts estrogenic agonist effects on nonbreast tissues, which influences the overall therapeutic index of the drug. Therefore, several novel antiestrogen compounds that offer the potential for enhanced efficacy and reduced toxicity compared with tamoxifen have been developed. These novel antiestrogens can be divided into tamoxifen analogues (e.g., toremifene, droloxifene, idoxifene); “fixed-ring” compounds (e.g., raloxifene, bazedoxifene, lasofoxifene, arzoxifene, mirexifene, levormeloxifene); and the SERDs (e.g., fulvestrant), the latter also termed “pure antiestrogens” (Howell et al., 2004; McDonnell and Wardell, 2010).

**Tamoxifen.** Tamoxifen was developed as an oral contraceptive but instead was found to induce ovulation and to have antiproliferative effects on estrogen-dependent breast cancer cell lines (Jordan, 2006). Tamoxifen is prescribed for the adjuvant therapy of early-stage breast cancer (Early Breast Cancer Trialists’ Collaborative Group, 2011) and for the therapy of advanced breast cancer (Burstein et al., 2010). Tamoxifen and other SERMs such as raloxifene are also used for the prevention of breast cancer in high-risk patients such as those with a strong family history or prior nonmalignant breast pathology (Visvanathan et al., 2013). The uses,

suppression of ovarian function with GnRH analogues (Table 68–2) typically given in combination with either tamoxifen or an AI. These combinations used in premenopausal women further reduce estrogen stimulation of breast cancer and result in lower rates of disease recurrence in very young women and in patients receiving chemotherapy (Francis et al., 2015). Some studies suggested improved response rates with these combinations in patients with metastatic disease. Tamoxifen also has shown effectiveness (a 40%–50% reduction in tumor incidence) in preventing breast cancer in women at increased risk (Fisher et al., 1998). In the preventive setting, tamoxifen reduces

---

**Figure 68–1**  Tamoxifen and its metabolites.
Toxicity. The common adverse reactions to tamoxifen include vasomotor symptoms (hot flashes), atrophy of the lining of the vagina, menstrual irregularities, vaginal bleeding and discharge, and pruritus vulvae and occur with increasing severity in postmenopausal women. Because of partial agonist activity, tamoxifen also increases the incidence of endometrial cancer by 2- to 3-fold, particularly in postmenopausal women who receive tamoxifen for more than 2 years. Tamoxifen slightly increases the risk of thromboembolic events, which increase with the age of a patient and also in the perioperative period. Hence, it often is advisable to temporarily halt tamoxifen prior to elective surgery. Tamoxifen can cause retinal deposits, decreased visual acuity, and cataracts, although these changes are uncommon.

Endocrine Resistance. Initial or acquired resistance to endocrine therapies (tamoxifen or AIs) frequently occurs (Moy and Goss, 2006). Multiple mechanisms contribute to endocrine resistance in breast cancer (Clarke et al., 2015); these mechanisms include loss of ER expression, changes in coregulator expression, and hormone-independent activation of the ER by stress kinase or growth factor–activated cellular kinase pathways. In particular, cross talk between the ER and the HER2/neu pathway has been implicated in tamoxifen resistance. In a significant portion of metastatic breast cancers, estrogen-deprivation therapy can lead to selection of cancer cells expressing an ER with mutations that allow hormone-independent activation. Acquired ER mutations also contribute to endocrine-resistant breast cancer growth (Jeselsohn et al., 2015).

Toremifene. Toremifene is a triphenylethylene derivative of tamoxifen and has a similar pharmacological profile, clinical efficacy, and safety (Howell et al., 2004). Toremifene is used occasionally in the metastatic and hormonally sensitive setting for the treatment of breast cancer in women with tumors that are ER+ or of unknown receptor status. In rare cases, toremifene can cause heart rhythm problems through prolongation of the QT interval.

**Selective Estrogen Receptor Downregulators.** The SERDS, also termed pure antiestrogens, include fulvestrant and a number of agents in experimental trials. SERDs, unlike SERMs, are devoid of any estrogen agonist activity.

**Fulvestrant.** Fulvestrant is currently the only FDA-approved SERD, either as a single agent or in combination with palbociclib, a CDK4/6 inhibitor (Chapter 67), for postmenopausal women with HR+ metastatic breast cancer that has progressed on antiestrogen therapy.

**Mechanism of Action.** Fulvestrant is a steroidal antiestrogen that binds to the ER with an affinity more than 100 times that of tamoxifen. The drug not only inhibits the binding of estrogen but also alters the receptor structure such that the receptor is targeted for proteasomal degradation; fulvestrant also may inhibit receptor dimerization. Unlike tamoxifen, which stabilizes or even increases ER expression, fulvestrant reduces the number of ER molecules in cells; as a consequence of this ER downregulation, the drug abolishes ER-mediated transcription of estrogen–dependent genes.

**ADME.** Fulvestrant is given intramuscularly with initial biweekly loading doses in the first month followed by once monthly injections thereafter. Using this dosing regimen, steady-state levels are achieved within the first month (Robertson et al., 2014) (Table 68–1). Peak plasma concentrations are reached about 7 days after intramuscular administration of fulvestrant and the plasma t1/2 is about 40 days. There is rapid distribution and extensive protein binding of this highly lipophilic drug. Various pathways, similar to those of steroid metabolism (oxidation, aromatic hydroxylation, and conjugation), metabolize fulvestrant. CYP3A4 appears to be the major CYP isozyme involved in the metabolism of fulvestrant. The putative metabolites possess no estrogenic activity, and only the 17-keto compound demonstrates a level of antiestrogenic activity (~22% that of fulvestrant). Less than 1% of the parent drug is excreted intact in the urine.

**Therapeutic Uses.** Fulvestrant is used in postmenopausal women as antiestrogen therapy of HR+ metastatic breast cancer after progression on first-line antiestrogen therapy such as tamoxifen or an AI. Fulvestrant is at least as effective in this setting as the third-generation AI anastrozole. Recently, the addition of a CDK4/6 inhibitor (Chapter 67) to fulvestrant...
Aromatase converts androgens to estrogens (e.g., androstenedione to estrone). AIs (Figure 68–2) block this enzymatic activity, thereby reducing estrogen production (Figure 67–3). AIs are now considered the standard of care for adjuvant treatment of postmenopausal women with ER+ breast cancer, either as initial therapy or after tamoxifen. (Dowsett et al., 2010). AIs are also approved in the initial treatment of metastatic HR+ breast cancer, often in combination with CDK4/6 inhibitors, and for disease that has progressed following tamoxifen treatment in postmenopausal women.

Aromatase (CYP19A1) is responsible for the conversion of adrenal androgens and gonadal androstenedione and testosterone to the estrogens estrone (E1) and estradiol (E2), respectively (Figure 68–3; reactions catalyzed by aromatase are noted by a green A beside the reaction arrow). In postmenopausal women, this conversion occurs in nonovarian tissues (fat, liver, muscle, brain, breast, and breast tumors) and is the primary source of circulating estrogens. In premenopausal women, estrogen is primarily produced in the ovaries. AIs increase gonadotropin production in premenopausal women, which reduces their ability to inhibit ovarian estrogen production. As a result, AIs are not effective in premenopausal women without additional ovarian suppression (e.g., with GnRH analogues; see the next section and Table 68–2). In postmenopausal women, AIs suppress most peripheral aromatase activity, leading to profound estrogen deprivation. AIs are classified as first, second, or third generation. In addition, they are further classified as type 1 (steroidal) or type 2 (nonsteroidal) AI according to their structure and mechanism of action (Figure 68–2). Type 1 inhibitors are steroidal analogues of androstenedione that bind covalently and irreversibly to the same site on the aromatase molecule. Thus, they commonly are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal and bind reversibly to the heme group of the enzyme, producing reversible inhibition.

**Drugs That Decrease Estrogen Levels**

**Aromatase Inhibitors.** Aromatase trihydroxylates the methyl group at C19, eliminating it as formate and aromatizing the A ring of the androgen substrate. Type 1 AIs are steroidal analogues of androstenedione that bind covalently and irreversibly to the steroid substrate site on the enzyme and are known as aromatase inactivators. Type 2 inhibitors are nonsteroidal, bind reversibly to the heme group of the enzyme, and produce reversible inhibition.

**Third-Generation Aromatase Inhibitors.** First- and second-generation (e.g., aminoglutethimide, formestane) AIs are no longer used for breast cancer treatment because of their side effects. Third-generation AIs are used as part of the treatment of early-stage and advanced breast cancer in postmenopausal women and for chemoprevention (Table 68–1). The type 1 and 2 AIs have similar clinical efficacy and toxicity profiles (Goss et al., 2013), and these are summarized for AIs using anastrozole as a prototype. For letrozole and exemestane, additional drug-specific information is given.

• **Anastrozole.** Anastrozole is a potent and selective triazole AI. Anastrozole, like letrozole, binds competitively and specifically to the heme of the CYP19. Daily administration of AIs reduces total body androgen aromatization by more than 95% after 1 month of treatment. AIs also reduce aromatization within large ER+ breast tumors.

• **ADME.** Anastrozole is absorbed rapidly after oral administration. Steady state is attained after 7 days of repeated dosing. Anastrozole is metabolized by N-dealkylation, hydroxylation, and glucuronidation. The main metabolite of anastrozole is a triazole. Less than 10% of the drug is excreted as the unmetabolized parent compound. The principal excretory pathway is via the liver and biliary tract. The elimination half-life is about 50 h. The pharmacokinetics of anastrozole, which can be affected by drug interactions via the CYP system, are not altered by coadministration of tamoxifen or cimetidine.

• **Therapeutic Uses.** AIs are approved for up-front adjuvant hormonal therapy for 5–10 years or following prior tamoxifen in postmenopausal women with early-stage breast cancer and as treatment of advanced and metastatic breast cancer. In early-stage breast cancer, anastrozole is significantly more effective than tamoxifen in delaying time to recurrent disease.
**Therapeutic Uses.** Most adverse effects are related to ADME.

The clinical indications for use of letrozole in breast cancer treatment are the same as for anastrozole (Table 68–1).

In addition, improved progression-free survival is observed when HR+ advanced stage breast cancer is treated with letrozole in combination with a CDK4/6 inhibitor (Chapter 67) (Hortobagyi et al., 2016).

- **Exemestane.** Exemestane is a more potent, orally administered analogue of the natural aromatase substrate androstanedione and lowers estrogen levels more effectively than does its predecessor, formestane. Exemestane irreversibly inactivates aromatase and is a “suicide substrate” type 1 inhibitor of aromatase. The clinical uses and side-effect profile of exemestane are similar to that detailed in the section for the AI anastrozole. Exemestane-specific information is as follows:

  - **ADME.** Orally administered exemestane is rapidly absorbed from the GI tract; its absorption is increased by 40% after a high-fat meal. Exemestane has a terminal \( t_{1/2} \) of about 24 h. It is extensively metabolized in the liver, ultimately to inactive metabolites. One metabolite, 17-hydroxyexemestane, has weak androgenic activity that may contribute to antitumor activity. Although active metabolites are excreted in the urine, no dosage adjustments are recommended in patients with renal dysfunction.

  - **Therapeutic Uses.** The clinical indications for use of exemestane in breast cancer treatment are the same as for anastrozole (Table 68–1). In addition, the use of the mTOR inhibitor everolimus (Chapter 67) with exemestane has been approved for treatment of advanced-stage breast cancer that has progressed on nonsteroidal type 2 AIs (Yardley et al., 2013).

**GnRH Agonists.** Synthetic GnRH analogues (e.g., triptorelin, goserelin, leuprolide; Table 68–2) have greater receptor affinity and reduced susceptibility to enzymatic degradation than the naturally occurring decapeptide GnRH molecule and are 100-fold more potent GnRH agonists than the native decapetide. They are used in the adjuvant treatment of breast cancer or metastatic disease for women who have functioning ovaries; typically, they are used in combination with either tamoxifen or AIs. Continuous administration of GnRH agonists downregulates GnRH receptors in the pituitary gland. This suppresses the release of the gonadotropins FSH and LH from the pituitary and prevents follicular maturation.

**Figure 68–3** Steroid synthesis pathways. The shaded area contains the pathways used by the adrenal glands and gonads and clinically used agents that inhibit the pathways. Enzymes are labeled in green, inhibitors in red. Pertaining to this figure only, A, aromatase; 3β, 3β-hydroxysteroid dehydrogenase; 5αR, 5α-reductase; 11β, 11β-hydroxylase; 17, 20, C-17, 20-lyase (also CYP17); 17α, 17α-hydroxylase (CYP17); 17βR, 17β-reductase; 18, aldosterone synthase; 21, 21-hydroxylase.

- **Letrozole.** The clinical uses and side-effect profile of the type 2 AI letrozole are similar to that detailed in the previous section for anastrozole (Table 68–1). Letrozole-specific information is as follows:

  - **ADME.** Letrozole is rapidly absorbed after oral administration, with a bioavailability of 99.9%. Steady-state plasma concentrations of letrozole are reached after 2–6 weeks of treatment. Following metabolism by CYP2A6 and CYP3A4, letrozole is eliminated as an inactive metabolite mainly via the kidneys and has a \( t_{1/2} \) of about 41 h.

  - **Therapeutic Uses.** The clinical indications for use of letrozole in breast cancer treatment are the same as for anastrozole (Table 68–1).
in the ovary. Serum estrogen levels are reduced to those seen in postmeno-
pausal women or in women after oophorectomy.

**ADME.** GnRH agonists are administered as an injection once a month or every 3 or 6 months. There is in an initial rise in LH and FSH levels, but after 14–21 days of therapy, a sustained decrease in serum LH and estrogen is observed.

**Therapeutic Uses.** In the adjuvant setting, recent studies have demon-
strated a benefit for GnRH agonists when given in conjunction with either AIs or tamoxifen in very young or higher-risk premenopausal women (Ragan et al., 2016). In addition, these drugs can be given with tamoxifen, AIs, or fulvestrant in premenopausal women with metastatic breast cancer.

**Toxicity.** Side effects are generally related to hypoestrogenism (i.e., hot flashes, vaginal dryness, decreased libido, osteoporosis, amenorrhea, and dyspareunia). The side effects of GnRH agonists are potentially reversible on cessation of therapy. AI use in premenopausal women combined with ovarian suppression with GnRH analogues increases menopausal symp-
toms and sexual dysfunction and thus benefits and risks must be carefully
considered (Burstein et al., 2016).

**Drugs That Target the Progesterone Receptor**

Progestational agents (see Chapter 44 for details) are mainly used as sec-
ondary agents in hormonal therapy for metastatic hormone-dependent
breast cancer and are also used in the management of endometrial carci-
oma previously treated by surgery and radiotherapy. Progesterone binds
to the PR present in target issues, such as breast and the endometrium
(Chapter 44). Activation of the PR by progestins in the endometrium is antiproliferative.

**Medroxyprogesterone acetate** is available for oral administration; an
alternative oral progesterational agent is megestrol acetate. Beneficial effects
have been observed in one-third of patients with endometrial cancer. The
response of breast cancer to megestrol is predicted by both the presence of
HRs (ER and PR) and the evidence of response to a prior hormonal treat-
ment. The effect of progesterin therapy in breast cancer appears to be dose
dependent, with some patients demonstrating second responses following
dose escalation of megestrol. Clinical use of progestins in breast cancer has
been largely superseded by the advent of tamoxifen and AIs. An additional
use of progestins is to stimulate appetite and restore a sense of well-being
in cachectic patients with advanced stages of cancer and AIDS.

**Hormone Therapy of Prostate Cancer**

Androgens stimulate the growth of normal and cancerous prostate cells.
The critical role of androgens for prostate cancer growth was established
in 1941 and led to the awarding of a Nobel Prize in 1966 to Dr. Charles
Huggins. These findings established androgen deprivation therapy (ADT)
as the mainstay of treatment for patients with advanced prostate cancer.
ADT is also given in conjunction with radiation therapy or following
surgery for some men with regionally localized intermediate- to high-
risk disease. In patients with metastasis, ADT is typically the standard
first-line treatment. ADT is accomplished via surgical castration (bilateral
orchietomy) or medical castration (using GnRH agonists or antagonists).
Other hormone therapy approaches that are used as second-line treatment
include antiandrogens, estrogens, and inhibitors of steroidogenesis. In the
advanced setting, ADT is not a curative treatment but does prolong sur-
vival. ADT alleviates cancer-related symptoms and provides important
quality-of-life benefits, including reduction of bone pain and reduction
of rates of pathological fracture, spinal cord compression, and ureteral
obstruction.

Disease progression despite ADT signifies the development of castration-resistant prostate cancer (CRPC). In CRPC, the AR can be
overexpressed or mutated and can be activated by weak adrenal andro-
gens or from androgens produced locally in tumors. Therefore, anti-
androgens (competitive antagonists of androgens at the AR), inhibitors of
steroidogenesis, or estrogens are frequently employed as second-line
hormone therapies and are associated with improvements in symptoms
and quality of life and with prolongation in survival (Ritch and Cookson,
2016). Antiandrogens are typically administered concurrently with GnRH
analogues or in men who have undergone orchiectomy. When patients
become refractory to further hormonal therapies, their disease is consid-
ered androgen independent.

Common side effects of androgen deprivation include vasomotor instability, loss of libido, impotence, gynecomastia, fatigue, anemia, weight gain, decreased insulin sensitivity, altered lipid profiles, osteopo-
rosis and fractures, and loss of muscle mass. ADT is associated with a
slight but significant increased risk of diabetes and coronary heart disease.
Skeletal-related events due to ADT may be mitigated by bisphosphonate
therapy (see Chapter 48). Antiandrogens, when compared with GnRH
agonists, cause more gynecomastia, mastodynia, and hepatotoxicity but
less vasoconstriction and loss of bone mineral density. Estrogens cause
a hypercoagulable state and increase cardiovascular mortality in patients
with prostate cancer and are no longer standard treatment options.

**Androgen Deprivation Therapy**

**GnRH Agonists and Antagonists.** The most common form of ADT
involves chemical suppression of the pituitary gland with GnRH ago-
nists (see previous section). GnRH agonists in common use for prostate
cancer include leuprolide, goserelin, triptorelin, histrelin, and nafarelin
(Table 68–2). Long-acting preparations are available in doses that are
approved for 3-, 4-, and 6-month administrations.

The GnRH agonists bind to GnRH receptors on pituitary gonadotropin-producing cells, causing an initial release of both LH and
FSH and a subsequent increase in testosterone production from testicular
Leydig cells. After 1 week of therapy, GnRH receptors are downregulated
on the gonadotropin-producing cells, causing a decline in the pituitary
response. The fall in serum LH leads to a decrease in testosterone produc-
tion to castrate levels within 3–4 weeks of the first treatment. Subsequent
treatments maintain testosterone at castrate levels.

ADT is given in patients with localized intermediate- to high-risk pros-
tate cancer in conjunction with radiation therapy or in some cases fol-
lowing surgery. In patients with metastasis, ADT is typically the standard
first-line treatment either alone or in combination with chemotherapy.
In patients with CRPC, ADT is used in conjunction with antiandrogens.
This combination therapy is referred to as combined androgen blockade.
The theoretical advantage is that the GnRH agonist will deplete testicular
androgens, while the antiandrogen component competes at the receptor
with residual androgens made by the adrenal glands. Combined androgen
blockade provides maximal relief of androgen stimulation. Several trials
suggested a benefit in 5-year survival, but toxicity and costs associated
are higher than with ADT alone.

**Toxicity.** During the transient rise in LH, the resultant testoster-
one surge may induce acute stimulation of prostate cancer growth and a
"flare" of symptoms from metastatic deposits. Patients may experi-
ence an increase in bone pain, spinal cord compression, or obstructive
bladder symptoms lasting for 2–3 weeks. The flare phenomenon can be
effectively counteracted with concurrent administration of 2–4 weeks of
oral antiandrogen therapy, which may inhibit the action of the increased
serum testosterone levels. Besides avoidance of the initial flare, GnRH
agonist therapy offers no apparent advantage compared with GnRH
agonists. The early GnRH antagonists cetrorelix and abarelix (no longer
marketed), although effective, are now rarely used for prostate cancer
because of the risk for severe systemic allergic reactions. A newer GnRH
agonist, degarelix, is not associated with systemic allergic reactions and
is approved for prostate cancer in the U.S.

**Drugs That Target the Androgen Receptor.** Antiandrogens bind to ARs
and competitively inhibit the binding of testosterone and dihydrotestos-
terone, thereby preventing AR nuclear translocation and inhibiting tran-
scription of downstream androgen-responsive genes. Unlike castration,
antiandrogen therapy by itself does not decrease LH production; therefore,
testosterone levels are normal or increased. Men treated with antiandrogen
maintain some degree of potency and libido and do not have the same
spectrum of side effects seen with castration. However, antiandrogen
therapy is typically given in combination with ADT. Antiandrogens are
classified as steroidal, including cyproterone or nonsteroidal, including
enzalutamide, flutamide, bicalutamide, and nilutamide.
Enzalutamide. Enzalutamide is the most recently FDA-approved second-generation antiandrogen. It prolongs survival in patients with metastatic CRPC when given to chemotherapy-naive patients or after docetaxel therapy (Beer et al., 2014; Scher et al., 2012). Enzalutamide is a synthetic nonsteroidal antiandrogen that has 5- to 8-fold higher binding affinity for the AR compared to bicalutamide (Tran et al., 2009). Similar to other antiandrogens, enzalutamide prevents binding of androgens to the AR and reduces binding of AR to DNA and to AR coactivator proteins (see Chapter 45). Enzalutamide can also prevent translocation of AR into the cell nucleus and induces cell apoptosis.

- **ADME.** Enzalutamide has improved efficacy and potency compared to older antiandrogens. Enzalutamide is given orally once daily with a $t_{1/2}$ of approximately 6 days. Steady-state levels are achieved in 28 days. CYF2C8 is primarily responsible for the formation of the active metabolite N-desmethyl enzalutamide.

- **Toxicity.** Similar to other antiandrogens, enzalutamide has negative effects on sexual function. Other notable side effects include gynecomastia, breast pain, fatigue, diarrhea, headache, and hot flashes. Enzalutamide crosses the blood-brain barrier, and seizures occur infrequently in approximately 1% of patients. Resistance to AR inhibitors develops frequently through mechanisms such as gene rearrangement, mutation, and acquired AR splice variants (Li et al., 2013). Studies are ongoing with newer AR-blocking agents that may overcome resistance to current antiandrogen therapies (Moilanen et al., 2015; Smith et al., 2016).

Bicalutamide. The agent bicalutamide is given once daily in conjunction with a GnRH agonist. Bicalutamide has a $t_{1/2}$ of 5–6 days. Bicalutamide undergoes glucuronidation to inactive metabolites, and the parent compound and metabolites are eliminated in bile and urine. The $t_{1/2}$ of bicalutamide is increased in severe hepatic insufficiency and is unchanged in renal insufficiency. Bicalutamide is well tolerated at higher doses and has reduced toxicity and improved tolerability and pharmacokinetic profiles relative to flutamide and nilutamide. Daily bicalutamide is significantly inferior compared with surgical or medical castration and should not be used as monotherapy of prostate cancer.

Nilutamide. Nilutamide is given orally once daily. It has an elimination $t_{1/2}$ of 45 h and is metabolized to five products that are all excreted in the urine. Common side effects include mild nausea, alcohol intolerance (5%–20%), and diminished ocular adaptation to darkness (25%–40%); rarely, interstitial pneumonitis occurs.

Flutamide. Flutamide is given orally three times per day. It has a $t_{1/2}$ of 5 h; its major metabolite, hydroxyflutamide, is biologically active. Common side effects include diarrhea, breast tenderness, and nipple tenderness. Less commonly, nausea, vomiting, and hepatotoxicity occur. Rare reports of fatal hepatotoxicity have been observed. It is used infrequently as it has the least-favorable toxicity profile of the antiandrogens.

**Drugs That Inhibit Androgen Synthesis.** In the castrate state, AR signaling, despite low steroid levels, supports continued prostate cancer growth. AR signaling may occur due to androgens produced from nongonadal sources, AR gene mutations, or AR gene amplification. Nongonadal sources of androgens include the adrenal glands and the prostate cancer cells themselves (see Figure 68–3). Androstenedione, produced by the adrenal glands, is converted to testosterone in peripheral tissues and tumors. Intratumoral de novo androgen synthesis also may provide sufficient androgen for AR-driven cell proliferation. Thus, inhibitors of androgen synthesis may be useful as secondary therapy in reducing AR signaling.

**Ketoconazole.** Ketoconazole is an antifungal agent that also inhibits both testicular and adrenal steroidogenesis by blocking CYP11A and primarily CYP17 (17α-hydroxylase). Ketoconazole is administered off label as secondary hormone therapy to reduce adrenal androgen synthesis in CRPC. Diarrhea and hepatic enzyme elevations limit its use as initial hormone therapy; consequent poor patient compliance reduces its efficacy. Oral ketoconazole is coadministered with hydrocortisone to compensate for inhibition of adrenal steroidogenesis. Ketoconazole has limited use in practice due to its toxicity.

**Abiraterone.** Abiraterone is used with prednisone for the treatment of CRPC in patients who are chemotherapy-naive or in those who have received previous docetaxel. In both settings, it prolongs survival (de Bono et al., 2011; Ryan et al., 2015).

- **Mechanism of Action.** Abiraterone is an irreversible inhibitor of 17α-hydroxylase and C-17,20-lyase (CYP17A1) activity in testicular, adrenal and prostatic cancer tissue (Figure 68–3). Abiraterone inhibition of CYP17A1 reduces the conversion of pregnenolone and progesterone to their 17α-hydroxy derivatives and reduces the synthesis of DHEA and androstenedione. Thus, circulating levels of testosterone drop to almost-undetectable levels after abiraterone administration. Abiraterone also has some activity as an AR antagonist and inhibitor of other steroid synthetic enzymes and CYP450s. Overall, abiraterone has greater potency and selectivity than ketoconazole.

- **ADME.** Abiraterone is the active metabolite of abiraterone acetate. With continuous administration, abiraterone increases ACTH levels, resulting in mineralocorticoid excess. Oral abiraterone acetate is administered with prednisone to counteract adrenal suppression. Abiraterone should be taken on an empty stomach. Abiraterone $C_{ss}$ and AUC are both increased more than 10-fold when a single dose of abiraterone acetate is administered after food compared to a fasted state.

- **Toxicity.** Side effects include hepatotoxicity, joint swelling, hypokalemia, vasomotor symptoms, diarrhea, cough, hypertension, arthrythmia, urinary frequency, dyspepsia, and upper respiratory tract infection. Resistance to abiraterone, similar to enzalutamide, can occur through selection of tumor cells expressing constitutively active AR splice variants (Antonarakis et al., 2014).

**Estrogens.** High estrogen levels can reduce testosterone to castrate levels in 1–2 weeks via negative feedback on the hypothalamic-pituitary axis. Estrogen also may compete with androgens for steroid HRs and may thereby exert a cytotoxic effect on prostate cancer cells. Although estrogens reduce bone loss and are as effective as orchectomy for metastatic prostate cancer, they are no longer used clinically because of their risk for serious and potentially fatal side effects (e.g., myocardial infarctions, strokes, pulmonary emboli) as well as impotence and lethargy.

**Acknowledgment:** Paul Calabresi, Bruce Chabner, Beverly Moy, Richard J. Lee, and Matthew Smith contributed to this chapter in recent editions of this book. We have retained some of their text in the current edition.

Special Systems Pharmacology

Chapter 69. Ocular Pharmacology / 1251
Chapter 70. Dermatological Pharmacology / 1271
Chapter 71. Environmental Toxicology: Carcinogens and Heavy Metals / 1297
The eye is a specialized sensory organ that is relatively secluded from systemic access by the blood-retinal, blood-aqueous, and blood-vitreous barriers. As a consequence, the eye exhibits some unusual pharmacodynamic and pharmacokinetic properties.

**Extraocular Structures**

The eye is protected by the eyelids and by the orbit, a bony cavity of the skull that has multiple fissures and foramina that conduct nerves, muscles, and vessels (Figure 69–1). In the orbit, connective (i.e., Tenon’s capsule) and adipose tissues and six extraocular muscles support and align the eyes for vision. The retrobulbar region lies immediately behind the eye (or globe). Understanding ocular and orbital anatomy is important for safe periocular drug delivery, including subconjunctival, sub-Tenon, and retrobulbar injections.

The external surface of the eyelids is covered by a thin layer of skin; the internal surface is lined with the palpebral portion of the conjunctiva, which is a vascularized mucous membrane continuous with the bulbar conjunctiva. At the reflection of the palpebral and bulbar conjunctivae is a space called the fornix, located superiorly and inferiorly behind the upper and lower eyelids, respectively. Topical medications usually are placed in the inferior fornix, also known as the inferior cul-de-sac.

The lacrimal system consists of secretory glandular and excretory ductal elements (Figure 69–2). The secretory system is composed of the main lacrimal gland, which is located in the temporal outer portion of the orbit, and accessory glands located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 69–1 and Chapter 8). The parasympathetic innervation is clinically relevant because a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (see Chapter 15), and drugs used in the management of Parkinson disease (see Chapter 18). Muscarinic cholinergic and α adrenergic receptors that mediate responses of several pupillary muscles from Parkinson disease (see Chapter 18). Muscarinic cholinergic and α adrenergic receptors that mediate responses of several pupillary muscles from Parkinson disease (see Chapter 18).

The lacrimal system is composed of the main lacrimal gland which is located in the temporal outer portion of the orbit, and accessory glands located in the conjunctiva. The lacrimal gland is innervated by the autonomic nervous system (Table 69–1 and Chapter 8). The parasympathetic innervation is clinically relevant because a patient may complain of dry eye symptoms while taking medications with anticholinergic side effects, such as tricyclic antidepressants (see Chapter 15), and drugs used in the management of Parkinson disease (see Chapter 18). Muscarinic cholinergic and α adrenergic receptors that mediate responses of several pupillary muscles from Parkinson disease (see Chapter 18).

**Ocular Structures**

The eye is divided into anterior and posterior segments (Figure 69–3A). Anterior segment structures include the cornea, limbus, anterior and posterior chambers, trabecular meshwork, canal of Schlemm (Schlemm’s canal), iris, lens, ciliary zonule, and ciliary body. The posterior segment includes the vitreous, retina, choroid, sclera, and optic nerve.

**Anterior Segment**

**Cornea and Drug Access**

The cornea is a transparent and avascular tissue organized into five (or six) layers (Figure 69–3B). Representing an important barrier to foreign matter, including drugs, the hydrophilic epithelial layer comprises five or six cell layers. The basal epithelial cells lie on a basement membrane that is adjacent to Bowman’s layer, a distinct sheet of collagen fibers. Constituting about 90% of the corneal thickness, the stroma, a hydrophilic layer, is organized with collagen lamellae synthesized by keratocytes. Beneath the stroma lies Descemet’s membrane, the basement membrane of the corneal endothelium. A new corneal layer, Dua’s layer, has been proposed—a

ACh: acetylcholine
ADME: absorption, distribution, metabolism, excretion
ARMD: age-related macular degeneration
CA: carbonic anhydrase
CAI: carbonic anhydrase inhibitor
CMV: cytomegalovirus
CNS: central nervous system
COMT: catechol-O-methyltransferase
DME: diabetic macular edema
FDA: Food and Drug Administration
5FU: 5-fluorouracil
GSH: reduced glutathione
HIV: human immunodeficiency virus
IOP: intraocular pressure
IP3: inositol triphosphate
MAO: monoamine oxidase
NMDA: N-methyl-D-aspartate
PDE: phosphodiesterase
PG: prostaglandin
PK: phosphokinase
PLC: phospholipase C
RAR: retinoic acid receptor
RXR: retinoid X receptor
tPA: tissue plasminogen activator
VEGF: vascular endothelial growth factor

At the periphery of the cornea and adjacent to the sclera lies a transi- tional zone (1- to 2-mm wide) called the limbus. Limbal structures include the conjunctival epithelium, which contains the corneal epithelial stem cells; Tenon’s capsule; episclera; corneoscleral stroma; canal of Schlemm; and trabecular meshwork (see Figure 69–3B). Limbal blood vessels, as well as the tears, provide important nutrients and immunological defense mechanisms for the cornea. The anterior chamber holds about 250 μL of aqueous humor. The peripheral anterior chamber angle is formed by the cornea and the iris root. The trabecular meshwork and canal of Schlemm are located just above the apex of this angle. The posterior chamber, with about 50 μL of aqueous humor, is defined by the boundaries of the ciliary body processes, posterior surface of the iris, and lens surface.

Aqueous Humor Dynamics and Regulation of Intraocular Pressure

Aqueous humor is secreted by the ciliary processes and flows from the posterior chamber, through the pupil, and into the anterior chamber and leaves the eye primarily through the trabecular meshwork and canal of Schlemm, thence to an episcleral venous plexus and into the systemic circulation. This conventional pathway accounts for 80%–95% of aqueous humor outflow and is the main target for cholinergic drugs used in glaucoma therapy. Another outflow pathway is the uveoscleral route (i.e., fluid flows through the ciliary muscles and into the suprachoroidal space), which is the target of selective prostanoids (see Glaucoma in this chapter).

The peripheral anterior chamber angle is an important anatomical structure for differentiating two forms of glaucoma: open-angle glaucoma, which is by far the most common form of glaucoma in the U.S., and angle-closure or closed-angle glaucoma. Current medical therapy of open-angle glaucoma is aimed at decreasing aqueous humor production or increasing aqueous outflow. The preferred management for angle-closure glaucoma is surgical iridectomy, by either laser or incision, but short-term medical management may be necessary to reduce the acute IOP elevation and to clear the cornea prior to surgery. Long-term IOP reduction may be necessary, especially if the peripheral iris has permanently covered the trabecular meshwork.

In anatomically susceptible eyes, anticholinergic, sympathomimetic, and antihistaminic drugs can lead to partial dilation of the pupil and a change in the vectors of force between the iris and the lens. The aqueous humor then is prevented from passing from the posterior chamber.
through the pupil to the anterior chamber. The change in the lens-iris relationship leads to an increase in pressure in the posterior chamber, causing an anterior bowing of the iris, causing the iris root to be pushed against the angle wall, thereby covering the trabecular meshwork and closing the filtration angle and markedly elevating the IOP. The result is known as an acute attack of pupillary-block angle-closure glaucoma.

Iris and Pupil

The iris is the most anterior portion of the uveal tract, which also includes the ciliary body and choroid. The anterior surface of the iris is the stroma, a loosely organized structure containing melanocytes, blood vessels, smooth muscle, and parasympathetic and sympathetic nerves. Differences in iris color reflect individual variation in the number of melanocytes located in the stroma. Individual variation may be an important consideration for ocular drug distribution due to drug-melanin binding (see Distribution). The posterior surface of the iris is a densely pigmented bilayer of epithelial cells. Anterior to the pigmented epithelium, the dilator smooth muscle is oriented radially and is innervated by the sympathetic nervous system (Figure 69–4), which causes mydriasis (dilation). At the pupillary margin, the sphincter smooth muscle is organized in a circular band with parasympathetic innervation, which, when stimulated, causes miosis (constriction). The use of pharmacological agents to dilate normal pupils and to evaluate the pharmacological response of the pupil is summarized in Table 69–2. Agents affecting sympathetic neurotransmission in the eye are also used for the diagnostic evaluation of Horner syndrome and anisocoria.

Ciliary Body

The ciliary body serves two very specialized roles:

- Production and secretion of aqueous humor by the epithelial bilayer
- Accommodation by the ciliary muscle

The anterior portion of the ciliary body (pars plicata) comprises 70–80 ciliary processes with intricate folds. The posterior portion is the pars plana. The ciliary muscle is organized into outer longitudinal, middle radial, and inner circular layers. Coordinated contraction of this smooth muscle apparatus by the parasympathetic nervous system causes the zonular fibers suspending the lens to relax, allowing the lens to become more convex and to shift slightly forward. This process, known as accommodation, permits focusing on near objects and may be pharmacologically blocked by muscarinic cholinergic antagonists through a process called cycloplegia. Contraction of the ciliary muscle also puts traction on the scleral spur and hence widens the spaces within the trabecular meshwork. This last effect accounts for at least some of the IOP-lowering effect of directly acting and indirectly acting parasympathomimetic drugs. Blockade of β-adrenergic receptors of the ciliary epithelium decreases production of aqueous humor.

*Although acetylcholine and choline acetyltransferase are abundant in the corneal epithelium of most species, the function of acetylcholine in this tissue is unknown.

*The ciliary epithelium also is the target of carbonic anhydrase inhibitors. Carbonic anhydrase isoenzyme II is localized to both the pigmented and nonpigmented ciliary epithelium.

*Although β₂-adrenergic receptors mediate ciliary smooth muscle relaxation, there is no clinically significant effect on accommodation.
Lens

The lens is suspended by the ciliary zonule, specialized fibers emanating from the ciliary body. The lens is about 10 mm in diameter and is enclosed in a capsule. The bulk of the lens is composed of fibers derived from proliferating lens epithelial cells located under the anterior portion of the lens capsule. These lens fibers are continuously produced throughout life. Aging, in addition to certain medications, such as corticosteroids, and certain diseases, such as diabetes mellitus, cause the lens to become opacified, which is termed a cataract.

Posterior Segment

Because of the anatomical and vascular barriers to both local and systemic access, drug delivery to the eye’s posterior pole is particularly challenging.

Sclera and Choroid

The outermost coat of the eye, the sclera, covers the posterior portion of the globe. The external surface of the scleral shell is covered by an episcleral vascular coat, Tenon’s capsule, and the conjunctiva. The tendons of the six extraocular muscles insert collagen fibers into the superficial scleral. Numerous blood vessels pierce the sclera through emissaria to supply and drain the choroid, ciliary body, optic nerve, and iris. Inside the scleral shell, a capillary network (vascular choroid) nourishes the outer retina. Between the outer retina and the capillary network lie Bruch’s membrane and the retinal pigment epithelium, whose tight

*This percentage of pilocarpine is not commercially available and usually is prepared by the physician administering the test or by a pharmacist. This test also requires that no prior manipulation of the cornea (i.e., tonometry for measuring intraocular pressure or testing corneal sensation) be done so that the normal integrity of the corneal barrier is intact. Normal pupils will not respond to this weak dilution of pilocarpine; however, an Adie’s pupil manifests a denervation supersensitivity and is responsive to this dilute cholinergic agonist.
junctures provide an outer barrier between the retina and the choroid. The retinal pigment epithelium serves many functions, including vitamin A metabolism, phagocytosis of the rod outer segments, and multiple transport processes.

**Retina**
The retina is a thin, transparent, highly organized structure of neurons, glial cells, and blood vessels; it contains the photoreceptors and the rhodopsin-based G protein signaling system. The elevated IOP of glaucoma damages and causes the death of the ganglion cells (the optic nerve) that connect the retina and the brain. Glutamate, acting on NMDA receptors, can stimulate this process (Sucher et al., 1997). In theory, this offers a target for neuroprotective agents to protect against cell death, but to date no treatment other than IOP lowering has demonstrated any benefit in treating glaucoma.

**Vitreous**
Approximately 80% of the eye’s volume is the vitreous, a clear medium containing collagen type II, hyaluronic acid, proteoglycans, glucose, ascorbic acid, amino acids, and a number of inorganic salts.

**Optic Nerve**
The optic nerve is a myelinated nerve conducting the retinal output to the CNS. It comprises an intraocular portion, visible as the optic disk in the retina; an intraorbital portion; an intracanicular portion; and an intracranial segment. The nerve is ensheathed in meninges continuous with the brain. It is susceptible to a variety of insults, ranging from traumatic to toxic (ethambutol, methanol, ethanol) to nutritional (vitamin B	extsubscript{12}, folic acid deficiency) to infectious, neoplastic, and inflammatory. At present, pharmacological treatment of optic neuropathies usually is based on management of the underlying disease. For example, arteritic ischemic optic neuropathy (giant cell arteritis) is best treated with systemic glucocorticoids and optic neuritis with intravenous glucocorticoids (Beck et al., 2008). Management of the underlying disease also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver; thus, topical ophthalmic medications can cause significant systemic side effects, especially when used frequently or chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 69–5.

Transcorneal and subconjunctival/scleral absorption are the desired routes for localized ocular drug effects. The drug concentration gradient between the tear film and the cornea and conjunctival epithelium provides the driving force for passive diffusion across these tissues. Other factors that affect a drug’s diffusion are the size of the molecule, chemical structure, and steric configuration. Transcorneal drug penetration is a differential solubility process; the cornea resembles a trilaminar “fat-water-fat” structure corresponding to the epithelial, stromal, and endothelial layers, respectively. The epithelium and endothelium represent barriers for hydrophilic substances; the stroma is a barrier for hydrophobic compounds. Hence, an amphiphilic agent with both hydrophilic and lipophilic properties is best suited for transcorneal absorption. Drug penetration into the eye is

**Pharmacokinetics and Toxicology of Ocular Therapeutic Agents**

**Drug Delivery Strategies**
There are a number of formulations of agents and routes of drug administration that are unique to the eye (Figures 69–1 and Table 69–3).

Several formulations prolong the time a drug remains on the surface of the eye. These include gels, ointments, solid inserts, soft contact lenses, and collagen shields. Prolonging the time in the cul-de-sac beneath the eyelid enhances drug absorption. Ophthalmic gels (e.g., pilocarpine 4% gel) release drugs by diffusion following erosion of soluble polymers. Ointments usually contain mineral oil and a petrolatum base and are helpful in delivering antibiotics, cycloplegic drugs, or miotic agents. Solid inserts, such as the ganciclovir intravitreal implant, provide a zero-order rate of delivery by steady-state diffusion, whereby drug is released at a more constant rate over a prolonged period of time rather than as a bolus. Drug molecules may also be encapsulated in nanoparticles for controlled release on the ocular surface.

**ADME**
The ADME pharmacokinetic principles determine the time course of drug action in the eye; however, the routes of ocular drug administration, the flow of ocular fluids, and the architecture of the eye introduce other variables specific to the eye. Most ophthalmic medications are formulated to be applied topically. Drugs also may be injected by subconjunctival, sub-Tenon’s, intracorneal, intracameral, intravitreal, and retrobulbar routes.

**Absorption.** After topical instillation of a drug, the rate and extent of absorption are determined by the dwell time of the drug in the cul-de-sac and precorneal tear film, elimination by nasolacrimal drainage, drug binding to tear proteins, drug metabolism by tear and tissue proteins, and diffusion across the cornea and conjunctiva. A drug’s residence time may be prolonged by changing its formulation or vehicle. Residence time also may be extended by blocking the egress of tears from the eye by closing the tear drainage ducts with flexible silicone (punctal) plugs. Nasolacrimal drainage contributes to systemic absorption of topically administered ophthalmic medications. Absorption from the nasal mucosa avoids first-pass metabolism by the liver; thus, topical ophthalmic medications can cause significant systemic side effects, especially when used frequently or chronically. Possible absorption pathways of an ophthalmic drug following topical application to the eye are shown schematically in Figure 69–5.
Microbial preservatives such as benzalkonium chloride, chlorobutanol, and others alter drug penetration. Medication absorption usually is increased when an anatomical barrier is compromised or removed.

**Distribution.** Topically administered drugs may undergo systemic distribution primarily by nasal mucosal absorption and possibly via local ocular distribution by transcorneal/transconjunctival absorption. Following transcorneal absorption, the aqueous humor accumulates the drug, which then is distributed to intracocular structures and potentially to the systemic circulation via the trabecular meshwork pathway (see Figure 69–3B). Melanin binding of certain drugs is an important factor in some ocular compartments. For example, the mydriatic effect of a adrenergic agonists is slower in onset in humans with darkly pigmented irides compared to those with lightly pigmented irides; drug-melanin binding is a potential reservoir for sustained drug release. Another clinically important consideration for drug-melanin binding involves the retinal pigment epithelium. In the retinal pigment epithelium, accumulation of chloroquine (see Chapter 49) causes a toxic retinal lesion known as a “bull’s-eye” maculopathy, which is associated with a decrease in visual acuity. To reduce the risk of retinal toxicity from chloroquine and related substances (e.g., hydroxychloroquine), patients receiving chronic therapy should receive periodic eye exams and lifetime cumulative doses should generally be limited to 460 g of chloroquine and 1000 g of hydroxychloroquine.

**Metabolism.** Biotransformation of ocular drugs may be significant; a variety of enzymes, including esterases, oxidoreductases, lysosomal enzymes, peptidases, glucuronide and sulfate transferases, GSH-conjugating enzymes, COMT, MAO, and 11β-hydroxysteroid dehydrogenase are found in the eye. The esterases are of particular interest, permitting development of ester prodrugs for enhanced corneal permeability (e.g., latanoprost, latanostat). Local hygiene is the mainstay of therapy; topical antibiotics frequently are used. Systemic tetracycline, doxycycline, minocycline, erythromycin, and azithromycin often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

**Toxicity.** Most local toxic effects are due to hypersensitivity reactions or to direct toxic effects on the cornea, conjunctiva, periocular skin, and nasal mucosa. Eye drops and contact lens solutions commonly contain antimicrobial preservatives such as benzalkonium chloride, chlorobutanol, cause a punctate keratopathy or toxic ulcerative keratopathy. All ophthalmic medications are potentially absorbed into the systemic circulation (Figure 69–5), so systemic side effects may occur.

### Ophthalmic Uses of Drugs

#### Chemotherapy of Microbial Diseases in the Eye

**Bacterial Infections.** Infectious diseases of the skin, eyelids, conjunctivae, and lacrimal excretory system are encountered regularly. Periorcular skin infections are divided into preseptal and postseptal or orbital cellulitis. Depending on the clinical setting (e.g., preceding trauma, sinusitis, age of patient, relative immunocompromised state), oral or parenteral antibiotics may be administered in addition to topical medications. A number of antibiotics are formulated for topical ocular use (Table 69–4).

Dacryoadenitis, an infection of the lacrimal gland, is most common in children and young adults; it may be bacterial (typically *Staphylococcus aureus*, *Streptococcus spp.*) or viral (seen in mumps, infectious mononucleosis, influenza, and herpes zoster). When bacterial infection is suspected, systemic antibiotics usually are indicated.

Dacryocystitis is an infection of the lacrimal sac. In infants and children, the disease usually is unilateral and secondary to an obstruction of the nasolacrimal duct. In adults, dacryocystitis and canalicul infections may be caused by *S. aureus, Streptococcus spp.*, *diphtheroids, Candida spp.*, and *Actinomyces israelii*. Any discharge from the lacrimal sac should be sent for smears and cultures. Systemic antibiotics typically are indicated.

Infectious processes of the eyelids include hordeolum and blepharitis. A hordeolum, or stye, is an infection of the meibomian, Zeis, or Moll glands in the eyelids. The typical offending bacterium is *S. aureus*, and the usual treatment consists of warm compresses and topical antibiotic (gel, drops, or ointment). Blepharitis is a common bilateral inflammatory process of the eyelids characterized by irritation and burning, usually associated with a *Staphylococcus* sp. Local hygiene is the mainstay of therapy; topical antibiotics frequently are used. Systemic tetracycline, doxycycline, minocycline, erythromycin, and azithromycin often are effective in reducing severe eyelid inflammation but must be used for weeks to months.

Conjunctivitis is an inflammatory or infectious process of the conjunctiva that varies in severity from mild hyperemia to severe purulent discharge. The more common causes of conjunctivitis include viruses, allergies, environmental irritants, contact lenses, and chemicals. Less common causes include other infectious pathogens, immune-mediated reactions, associated systemic diseases, and tumors of the conjunctiva or eyelid. Commonly reported infectious agents are adenovirus and herpes simplex virus, followed by other viral (e.g., enterovirus, coxsackievirus, measles virus, varicella zoster virus) and bacterial sources (e.g., *Haemophilus*, *Streptococcus pneumoniae, Chlamydia trachomatis, and chlamydial spp.*). *Reckittis*, fungi, and parasites, in both cystic and trophozoite form, are rare causes of conjunctivitis. Effective management is based on selection of an appropriate antibiotic for suspected bacterial pathogens. Unless an unusual causative organism is suspected, bacterial conjunctivitis is treated empirically with a broad-spectrum topical antibiotic without obtaining a culture.

Keratitis, or corneal inflammation or infection, can occur at any level of the cornea. Myriad microbial agents may cause infectious keratitis, including bacteria, viruses, fungi, spirochetes, and parasites. Severe infections with tissue loss (corneal ulcers) generally are treated more aggressively than infections without tissue loss (corneal infiltrates). Mild, small, more peripheral infections usually are not cultured, and the eyes are treated with broad-spectrum topical antibiotics. In more severe, central, or larger infections, corneal scrapings for cultures and sensitivities are performed, and the patient is immediately started on intensive hourly, around-the-clock topical antibiotic therapy. A commercially available broad-spectrum antibiotic may be given, but in severe infections, specially formulated fortified antibiotics are often used. The goal of treatment is to eradicate the...

*BD, blood dyscrasia; D-RCD, drug-related corneal deposits; H, hypersensitivity.

bFor specific information on dosing, formulation, and trade names, refer to the Physicians’ Desk Reference for Ophthalmic Medicines, which is published annually.

cPolymin B is formulated for delivery to the eye in combination with bacitracin, neomycin, gramicidin, oxytetracycline, or trimethoprim. See Chapters 56–59 for further discussion of these antibacterial agents.

cTobramycin is formulated for delivery to the eye in combination with dexamethasone or loteprednol etabonate.

infection and reduce the amount of corneal scarring and the chance of corneal perforation and severe decreased vision or blindness. The initial medication selection and dosage are adjusted according to the clinical response and culture/sensitivity results. In the case of culture-proven bacterial keratitis that has been treated with appropriate topical antibiotics for a several days but still has significant inflammation, judicious topical steroids can be used with close follow-up to decrease corneal scarring.

Endophthalmitis is a potentially severe and devastating inflammatory, and usually infectious, process involving the intraocular tissues. When the inflammatory process encompasses the entire globe, it is called panophthalmitis. Endophthalmitis usually is caused by bacteria or fungi or rarely by spirochetes. The typical case occurs during the early postoperative course after intraocular surgery, following trauma, or rarely by endogenous seeding in an immunocompromised host or intravenous drug user. Acute postoperative endophthalmitis requires a prompt vitreous tap for smears and cultures and empirical injection of intravitreal antibiotics. In cases of endogenous seeding, parenteral antibiotics have a role in eliminating the infectious source; systemic antibiotics are helpful in reducing the risk of endophthalmitis following a traumatic open-globe injury (Ahmed et al., 2012). Vitrectomy (i.e., specialized surgical removal of the vitreous) is indicated in some cases (Endophthalmitis Vitrectomy Study Group, 1995; Schiedler et al., 2004).

Viral Infections

Antiviral drugs used in ophthalmology are summarized in Table 69–5 (see Chapter 62 for details of these agents). The primary indications for the use of antiviral drugs in ophthalmology are viral keratitis, herpes zoster ophthalmicus, and retinitis. There currently are no antiviral agents indicated for the treatment of viral conjunctivitis caused by adenoviruses, which usually has a self-limited course and typically is treated by symptomatic relief of irritation, but topical ganciclovir gel may be of some benefit (Yabiku et al., 2011).

Viral keratitis, an infection of the cornea that may involve either the epithelium or stroma, is most commonly caused by herpes simplex type I and varicella zoster viruses. Less common viral etiologies include herpes simplex type II, Epstein-Barr virus, and CMV. The topical antiviral agents trifluridine and ganciclovir are both indicated for the treatment of epithelial disease due to herpes simplex infection, but trifluridine is more toxic to the corneal epithelium. Topical glucocorticoids are contraindicated in herpetic epithelial keratitis due to active viral replication. In contrast, for herpetic disciform keratitis (predominantly a cell-mediated immune reaction), topical glucocorticoids often accelerate recovery. For recurrent herpetic stromal keratitis, there is clear benefit from treatment with oral antivirals such as acyclovir in reducing the risk of recurrence (Herpetic Eye Disease Study Group, 1997, 1998; Young et al., 2010).

Herpes zoster ophthalmicus is a latent reactivation of a varicella zoster infection in the first division of the trigeminal cranial nerve. Systemic acyclovir, valacyclovir, and famciclovir are effective in reducing the severity and complications of herpes zoster ophthalmicus (Cohen and Kessler, 2016).

Viral retinitis may be caused by herpes simplex virus, CMV, adenovirus, and varicella zoster virus. With antiretroviral therapy (see Chapter 64), CMV retinitis does not appear to progress when specific anti-CMV therapy is discontinued, but some patients develop an immune recovery uveitis. Treatment usually involves long-term parenteral administration of antiviral drugs. Intravitreal ganciclovir, injected or implanted as an insert, is an effective alternative to systemic use. Acute retinal necrosis and progressive outer retinal necrosis, most often caused by varicella zoster virus, can be treated by combinations of oral, intravenous, and intravitreal administration of antiviral medications (Newman and Gooding, 2013).

*Off-label use. For additional details, see Chapter 62.

**Fungal Infections**

The only currently available topical ophthalmic antifungal preparation is natamycin, a polyene. Other antifungal agents may be extemporaneously compounded for topical, subconjunctival, corneal intrastromal, intracameral, or intravitreal routes of administration (Table 69–6; see also Chapter 61). As with systemic fungal infections, the incidence of ophthalmic fungal infections has risen with the growing number of immunocompromised hosts. Fungal infections can involve the cornea, sclera, intraocular structures, canalicular, and orbit. Risk factors for fungal keratitis include trauma, chronic ocular surface disease, contact lens wear, and immuno-suppression (including topical steroid use). When fungal infection is suspected, samples of the affected tissues are obtained for smears, cultures, and sensitivities, and this information is used to guide drug selection.

**Protozoal Infections**

Parasitic infections involving the eye usually manifest themselves as a form of uveitis, an inflammatory process of either the anterior or posterior segments and, less commonly, as conjunctivitis, keratitis, and retinitis. In the U.S., the most commonly encountered protozoal infections include *Acanthamoeba* and *Toxoplasma gondii*. In contact lens wearers who develop keratitis, physicians should be highly suspicious of the presence of *Acanthamoeba*. Risk factors for *Acanthamoeba* keratitis include poor contact lens hygiene, wearing contact lenses in a pool or hot tub, and ocular trauma. Treatment usually consists of a combination of topical agents. The aromatic diamidines—propamidine isethionate in topical aqueous and ointment forms (not commercially available in the U.S.)—have been used successfully to treat this relatively resistant infectious keratitis. The cationic antiseptic agent polyhexamethylene biguanide also is used in drop form for *Acanthamoeba* keratitis; alternatively, topical chlorhexidine can be used; both drugs need to be prepared by a specialty compounding pharmacy. Oral imidazoles (e.g., itraconazole, fluconazole, ketoconazole, voriconazole) often are used in addition to the topical medications. Resolution of *Acanthamoeba* keratitis often requires many months of treatment (Chew et al., 2011; Hotz and Tandon, 2011).

Treatment of toxoplasmosis is indicated when inflammatory lesions encroach on the macula and threaten central visual acuity. Several regimens have been recommended with concurrent use of systemic steroids: (1) pyrimethamine, sulfadiazine, and folic acid (leucovorin); (2) pyrimethamine, sulfadiazine, clindamycin, and folic acid; (3) sulfadiazine and clindamycin; (4) clindamycin; and (5) trimethoprim–sulfamethoxazole with or without clindamycin. Other protozoal infections (e.g., giardiasis, leishmaniasis, malaria) and helminth infections are less common eye pathogens in the U.S. Systemic pharmacological management as well as vitrectomy may be indicated for selected parasitic infections (Maenz et al., 2014).

**Ophthalmic Use of Autonomic Agents, Eicosanoids, and Carbonic Anhydrase Inhibitors**

Autonomic drugs are used extensively for diagnostic and surgical purposes and for the treatment of glaucoma, uveitis, and strabismus. The autonomic agents used in ophthalmology and the responses (i.e., mydriasis, cycloplegia) to muscarinic cholinergic antagonists are summarized in Table 69–7. Table 69–8 presents some characteristics of eicosanoids used in ophthalmology.

**Glaucoma**

Glaucoma is characterized by progressive loss of retinal nerve fiber layer tissue and visual field loss. The optic nerve acquires a characteristic loss of the neuroretinal rim, frequently referred to as “cupping.” The prevalence of the disease is growing as populations age and increase around the world (Tham et al., 2014). Risk factors include increased IOP, positive family history of glaucoma, African American heritage, and possibly myopia, diabetes, and hypertension. Reducing IOP can delay glaucomatous nerve or field damage. Although markedly elevated IOPs (e.g., > 30 mm Hg) usually will lead to optic nerve damage, the optic nerves in certain patients (ocular hypertensives) apparently can tolerate IOPs in the mid-to-high 20s. Other patients have progressive glaucomatous optic nerve damage despite having IOPs in the normal range; this form of the disease sometimes is called *normal- or low-tension* glaucoma. Regardless of the initial level, reducing the IOP delays or prevents disease progression (Collaborative Normal-Tension Study Group, 1998a, 1998b; Ederer et al., 2004; Heijl et al., 2002; Kass et al., 2002; Miglior et al., 2005). At present, the pathophysiologic processes involved in glaucomatous optic nerve damage and the relationship to aqueous humor dynamics are not understood. Current
pharmacotherapies are targeted at decreasing the production of aqueous humor at the ciliary body and increasing outflow through the trabecular meshwork and uveoscleral pathways. There is no consensus on the best IOP-lowering technique (Musch et al., 2011). A stepped medical approach depends on the patient's health, age, and ocular status, with knowledge of systemic effects and contraindications for all medications. A stepped medical approach may begin with a topical PG analogue (Table 69–8).

Due to their once-daily dosing, low incidence of systemic side effects, and potent IOP-lowering effect, PG analogues have largely replaced β adrenergic receptor antagonists as first-line medical therapy for glaucoma. The PG analogues consist of latanoprost (Figure 69–6), travoprost, bimatoprost, tafluprost, and unoprostone (discontinued in the U.S.). PGF₂α reduces IOP but has intolerable local side effects. Modifications to the chemical structure of PGF₂α have produced analogues with a more acceptable side-effect profile. PGF₁α and its analogues (prodrugs that are hydrolyzed to PGF₁α) bind to receptors for PGF₁α (FP receptors) that link to the Gq/PLC–IP₃–Ca²⁺ pathway. This pathway is active in isolated human ciliary muscle cells. Other cells in the eye also may express FP receptors. Theories of IOP lowering by PGF₁α range from altered ciliary muscle tension to effects on trabecular meshwork cells to release of matrix metalloproteinases and digestion of extracellular matrix materials that may impede outflow tracts.

The β receptor antagonists (Table 69–7) are currently the next most common topical medical treatment. Nonselective β blockers bind to both β₁ and β₂ receptors and include timolol, levobunolol, metipranolol, and carteolol. The β₁-selective antagonist betaxolol is available for ophthalmic use but is less efficacious than the nonselective β blockers because the β receptors of the eye are largely of the β₂ subtype. However, betaxolol is less likely to cause bradycardia due to blockade of pulmonary β₂ receptors. In the eye, the targeted tissues are the ciliary body epithelium and blood vessels, where β₂ receptors account for 75%–90% of the total population. How β blockade leads to decreased aqueous production and reduced IOP is uncertain. Production of aqueous humor seems to be activated by a β receptor–mediated cyclic AMP–PKA pathway; β blockade blunts adrenergic activation of this pathway. Another hypothesis is that β blockers decrease ocular blood flow, which decreases the ultrafiltration responsible for aqueous production.

When there are medical contraindications to the use of PG analogues or β receptor antagonists, other agents, such as an a-adrenergic receptor agonist (see Table 69–7) or topical CAI (Table 69–9), may be used as first-line therapy. The α₁ adrenergic agonists appear to decrease IOP by reducing aqueous humor production and by enhancing both conventional (via an α₁ receptor mechanism) and uveoscleral outflow (perhaps via PG production) from the eye. The α₁ adrenergic agonist and clonidine derivative apraclonidine is a relatively selective α₁ adrenergic agonist that is highly ionized at physiological pH, does not cross the blood–brain barrier, and is thus relatively free of the CNS effects of clonidine. Brimonidine is a selective α₂ adrenergic agonist that is lipophilic, enabling easy corneal penetration. Both apraclonidine and brimonidine reduce aqueous production and may enhance some uveoscleral outflow. Both appear to bind to pre- and postsynaptic α receptors. By binding to the presynaptic receptors, the drugs reduce the amount of neurotransmitter release from sympathetic nerve stimulation and thereby lower IOP. By binding to postsynaptic α receptors, these drugs stimulate the Gₑ pathway, reducing cellular cyclic AMP production, thereby reducing aqueous humor production.

The development of a topical CAI was prompted by the poor side-effect profile of oral CAIs. Dorzolamide and brinzolamide both work by inhibiting CA (isof orm II), which is found in the ciliary body epithelium. Inhibition of CA reduces the formation of bicarbonate ions, which reduces fluid transport and thus IOP (Table 69–9). Any of these four drug classes can be used as additive second- or third-line therapy. In fact, the β receptor antagonist timolol has been combined with the CAI dorzolamide in a single medication and with the α₁ adrenergic agonist brimonidine. A recently released combination of brinzolamide/brimonidine is also an option. A latanoprost/timolol combination is widely available. Such combinations reduce the number of drops needed and may improve compliance.

Topical miotic agents (see Table 69–7) are less commonly used today because of their numerous side effects and inconvenient dosing. Miotics lower IOP by causing muscarinic-induced contraction of the ciliary muscle, which facilitates aqueous outflow. They do not affect aqueous production. Pilocarpine and carbachol are cholinomimetics that stimulate muscarinic receptors and are referred to as having a direct mechanism of action. Indirect agents such as ephedriphate are organophosphate inhibitors of acetylcholinesterase. Echotropiopate is relatively stable in aqueous solution and, by virtue of its quaternary ammonium structure, is positively charged and poorly absorbed. If combined topical therapy fails to achieve the target IOP or fails to halt glaucomatous optic nerve damage, then systemic therapy with a CAI is a final medication option before resorting to laser or incisional surgical treatment. The best-tolerated oral preparation is acetazolamide in sustained-release capsules (see Chapter 25), followed by methazolamide. The least well tolerated are acetazolamide tablets.

| **α Adrenergic agonists** | | | |
| Phenylephrine | 2.5% and 10% solution | Mydriasis, vasoconstriction, decongestion, bradycardia, hypertension | α Adrenergic agonist effect lasts several hours; 2.5% used with tropicamide for office exams |
| Apraclonidine | 0.5% and 1% solution | Glaucoma, ocular hypertension | α adrenergic agonist; side effects: allergy (conjunctival hyperemia), dry mouth, sleepiness |
| Brimonidine (α2 selective) | Solution (0.1%–0.2%); 0.33% gel; also with timolol or brinzolamide | Glaucoma, ocular hypertension | Same as for apraclonidine; causes respiratory depression in young children |
| Naphazoline | 0.1% solution | Decongestant | Contraindicated in closed-angle glaucoma; safety/efficacy not established in neonates and children < 6 years; use with caution in patients with coronary artery disease, hypertension, hyperthyroidism, or diabetes |
| Tetrahydrozoline | 0.05% solution | Decongestant | Contraindicated in closed-angle glaucoma; safety/efficacy not established in neonates and children < 6 years; use with caution in patients with coronary artery disease, hypertension, hyperthyroidism, or diabetes |
| **β Adrenergic antagonists** | | | |
| Betaxolol (β1 selective) | 0.25% suspension, 0.5% solution | Glaucoma, ocular hypertension | Reduced incidence of respiratory problems compared to timolol |
| Timolol | Solution, gel (0.25%, 0.5%); also with brimonidine, dorzolamide, latanoprost | Glaucoma, ocular hypertension | Side effects: exacerbation of respiratory problems (asthma and chronic obstructive pulmonary disease), bradycardia, depression, impotence |
| Carteolol | 1% solution | Glaucoma, ocular hypertension | Same as timolol |
| Levobunolol | 0.25% and 0.5% solution | Glaucoma, ocular hypertension | |
| Metipranolol | 0.3% solution | Glaucoma, ocular hypertension | |

a Mydriasis and cycloplegia, or paralysis of accommodation, of the human eye occurs after one drop of atropine 1%, scopolamine 0.5%, homatropine 1%, cyclopentolate 0.5% or 1%, and tropicamide 0.5% or 1%. Recovery of mydriasis is defined by return to baseline pupil size to within 1 mm. Recovery of cycloplegia is defined by return to within 2 -diopters of baseline accommodative power. The maximal mydriatic effect of homatropine is achieved with a 5% solution, but cycloplegia may be incomplete. Maximal cycloplegia with tropicamide may be achieved with a 1% solution. Times to development of maximal mydriasis and to recovery, respectively, are as follows: for atropine, 30–40 min and 7–10 d; for scopolamine, 20–130 min and 3–7 d; for homatropine, 40–60 min and 1–3 d; for cyclopentolate, 30–60 min and 1 d; for tropicamide, 20–40 min and 6 h. Times to development of maximal cycloplegia and to recovery, respectively, are as follows: for atropine, 30–180 min and 6–12 d; for scopolamine, 30–60 min and 3–7 d; for homatropine, 30–60 min and 1–3 d; for cyclopentolate, 25–75 min and 6 h to 1 d; for tropicamide, 30 min and 6 h.

b Off label use. Refer to Physicians’ Desk Reference for Ophthalmic Medicines for specific indications and dosing.

**Toxicity of Antiglaucoma Agents.** Ciliary body spasm is a muscarinic cholinergic effect that can lead to induced myopia and a changing refraction due to iris and ciliary body contraction as the drug effect waxes and wanes between doses. Headaches can occur from the iris and ciliary body contraction. The α2 agonists, effective in IOP reduction, can cause a vasoconstriction-vasodilation rebound phenomenon, leading to a red eye. Ocular and skin allergies from topical epinephrine, apraclonidine, and brimonidine are common (epinephrine for ophthalmic use is no longer marketed in the U.S.). Brimonidine is less likely to cause ocular allergy and therefore is more commonly used. These agents can cause CNS depression and apnea in neonates and are contraindicated in children less than 2 years of age. Systemic absorption of α2 agonists and β adrenergic antagonists can induce all the side effects of systemic administration. The use of CAIs systemically may give some patients significant problems with malaise, fatigue, depression, paresthesias, and nephrolithiasis; the topical CAIs may minimize these relatively common side effects.

**Uveitis**

Inflammation of the uvea, or uveitis, has both infectious and noninfectious causes, and medical treatment of the underlying cause (if known), in addition to the use of topical therapy, is essential. Cyclopentolate, tropicamide, or sometimes even longer-acting antimuscarinic agents such as atropine, scopolamine, and homatropine frequently are used to prevent posterior synchiae formation between the lens and iris margin and to relieve ciliary muscle spasm that is responsible for much of the pain associated with anterior uveitis.

If posterior synchiae already have formed, an α adrenergic agonist may be used to break the synchiae by enhancing pupillary dilation. A solution of scopolamine 0.3% in combination with 10% phenylephrine is available for this purpose. Two others, 1% hydroxyamphetamine hydrobromide combined with 0.25% tropicamide and 1% phenylephrine in combination with 0.2% cyclopentolate, are indicated only for induction of mydriasis. Topical steroids usually are adequate to decrease inflammation but sometimes must be supplemented with systemic steroids.

**Strabismus**

Strabismus, or ocular misalignment, has numerous causes and may occur at any age. Besides causing diplopia (double vision), strabismus in children may lead to amblyopia (reduced vision). Nonsurgical efforts to treat amblyopia include occlusion therapy, orthoptics, optical devices, and pharmacological agents.

An eye with hyperopia, or farsightedness, must constantly accommodate to focus on distant images. In some hyperopic children, the synkinetic accommodative-convergence response leads to excessive convergence and a manifest esotropia (turned-in eye). The brain rejects diplopia and suppresses the image from the deviated eye. If proper vision is not restored by about 6–8 years of age, the brain never learns to process visual information from that eye. The result is that the eye appears structurally normal but does not develop normal visual acuity and is therefore amblyopic. This is a fairly common cause of visual disability. In this setting, atropine (1%) instilled in the preferred seeing eye produces cycloplegia and the inability of this eye to accommodate, thus forcing the child to use the amblyopic eye (Pediatric Eye Disease Investigator Group, 2002, 2003). Echothiophate iodide also has been used in the setting of accommodative strabismus. Accommodation drives the near reflex, the triad of miosis, accommodation, and convergence. An irreversible cholinesterase inhibitor such as echothiophate causes miosis and an accommodative change in the shape of the lens; hence, the accommodative drive to initiate the near reflex is reduced, and less convergence will occur.

**Surgical and Diagnostic Uses**

For certain surgical procedures and for clinical funduscopic examination, it is desirable to maximize the view of the retina and lens. Muscarinic cholinergic antagonists and sympathomimetic agents frequently are used singly or in combination for this purpose (see Table 69–7). Intraoperatively, there are circumstances in which miosis is preferred, and two cholinergic agonists are available for intraocular use, acetylcholine and carbachol. Patients with myasthenia gravis may first present to an ophthalmologist with complaints of double vision (diplopia) or eyelid droop (ptosis); the edrophonium test is helpful in diagnosing these patients (see Chapter 10). Intraoperatively, trypan blue is marketed (as 0.06% and 0.15% ophthalmic solutions) to facilitate visualization of the anterior lens capsule during cataract surgery and for staining the retinal surface during surgical vitrectomy to guide the excision of tissue.

**Anti-inflammatory, Immunomodulatory, and Antimitotic Drugs**

**Glucocorticoids**

Glucocorticoids have an important role in managing ocular inflammatory diseases (Table 69–10 and Table 69–11). The chemistry and pharmacology of glucocorticoids are described in Chapter 46.

**Therapeutic Uses.** The glucocorticoids formulated for topical administration to the eye are dexamethasone, prednisolone, fluorometholone, loteprednol, rimexolone, and difluprednate. Because of their anti-inflammatory effects, topical corticosteroids are used in managing significant ocular allergy, external eye inflammatory diseases associated with some infections and ocular cicatricial pemphigoid, anterior uveitis, and

*Off-label use.

postoperative inflammation following refractive, corneal, and intraocular surgery. After glaucoma filtering surgery, topical steroids can delay the wound-healing process by decreasing fibroblast infiltration, thereby reducing potential scarring of the surgical site. Steroids commonly are given systemically and by sub-Tenon’s capsule injection to manage posterior uveitis. Intravitreal injection of steroids is used to treat ARMD, diabetic retinopathy, and cystoid macular edema. An intravitreal triamcinolone formulation is approved for ocular inflammatory conditions unresponsive to topical corticosteroids and visualization during vitrectomy. Parenteral steroids followed by tapering oral doses is the preferred treatment of optic neuritis. Two ophthalmic implants, fluocinolone and dexamethasone, are marketed for the treatment of chronic, noninfectious uveitis; a dexamethasone implant is also indicated for the treatment of macular edema.

**Toxicity.** Ocular complications include the development of posterior subcapsular cataracts, secondary infections, and secondary open-angle glaucoma. There is a significant increase in the risk for developing secondary glaucoma when there is a positive family history of glaucoma. In the absence of a family history of open-angle glaucoma, only about 5% of normal individuals respond to topical or long-term systemic steroids with a marked increase in IOP. With a positive family history, however, moderate-to-marked steroid-induced IOP elevations may occur in up to 90% of patients. Some topical steroids (e.g., loteprednol) have been developed that reduce, but do not eliminate, the risk of elevated IOP.

### Nonsteroidal Anti-Inflammatory Agents

Pharmacological properties of NSAIDS are presented in Chapter 38. Five topical NSAIDS are approved for ocular use: flurbiprofen, ketorolac, dicyfenac, bromfenac, and nepafenac.

The NSAIDS are supplied as solutions and suspensions for topical ocular use to reduce ocular inflammation and cystoid macular edema. Flurbiprofen is used to counter unwanted intraoperative miosis during cataract surgery. Ketorolac is given for seasonal allergic conjunctivitis. A combination ketorolac/phenylephrine intraocular solution is available to add to intraoperative ophthalmic irrigation solutions to decrease miosis during cataract surgery. Diclofenac is used for postoperative inflammation and pain. Both ketorolac and dicyfenac are effective in treating cystoid macular edema occurring after cataract surgery and in controlling pain after corneal refractive surgery. Bromfenac and nepafenac are indicated for treating postoperative pain and inflammation after cataract surgery. Topical and systemic NSAIDS occasionally have been associated with sterile corneal melts and perforations, especially in older patients with ocular surface disease, such as dry eye syndrome.
Antihistamines and Mast Cell Stabilizers

H\textsubscript{1} antagonists (see Chapter 32) and mast cell stabilizers are used to treat the manifestations of ocular allergies. Pheniramine (see Chapter 32) and antazoline (discontinued in the U.S.) are formulated in combination with naphazoline, a vasoconstrictor, for relief of allergic conjunctivitis; medastin difumarate also is used. Cromolyn sodium has found some use in treating conjunctivitis that is thought to be allergen mediated, such as vernal conjunctivitis. The mast cell stabilizer lodoxamide tromethamine is available for ophthalmic use for the treatment of ocular inflammatory states such as vernal conjunctivitis and keratitis. Nedocromil, primarily a mast cell stabilizer with some antihistaminic properties, is also used. Likewise, olopatadine hydrochloride, ketotifen fumarate, bepotastine, azelastine, and alcaftadine are H\textsubscript{1} antagonists with mast cell-stabilizing properties. Epinastine antagonizes H\textsubscript{1} and H\textsubscript{2} receptors and exhibits mast cell-stabilizing activity.

Immunosuppressants

Topical cyclosporine (Table 69–12) is approved for the treatment of chronic dry eye associated with inflammation. Use of cyclosporine is associated with decreased inflammatory markers in the lacrimal gland, increased tear production, and improved vision and comfort. Topical lifitegrast (Table 69–12) is approved to treat the signs and symptoms of dry eye disease. Lifitegrast inhibits an integrin, lymphocyte function-associated antigen 1 (LFA-1), from binding to intercellular adhesion molecule 1 (ICAM-1) which is thought to down-regulate inflammation mediated by

T lymphocytes. Interferon α₂ is used off label in the treatment of conjunctival papilloma and certain conjunctival tumors.

**Antimitotic Agents**

In glaucoma surgery, the antineoplastic agent 5FU and mitomycin (Table 69–12; see details of mechanism in Chapter 66) improve the success of filtration surgery by limiting the postoperative wound-healing process.

**Therapeutic Uses.** Mitomycin is used intraoperatively as a single subconjunctival application at the trabeculectomy site. 5FU may be used intraoperatively at the trabeculectomy site or subconjunctivally during the postoperative course (Fluorouracil Filtering Surgery Study Group, 1996). Both agents work by limiting the healing process; sometimes this can result in thin, ischemic, avascular tissue that is prone to breakdown. The resultant leaks can cause hypotony (low IOP) and increase the risk of infection. In corneal surgery, mitomycin has been used topically. Mitomycin can be used to reduce the risk of scarring after procedures to remove corneal opacities and prophylactically to prevent corneal scarring after photorefractive and phototherapeutic keratectomy. Mitomycin also is used to treat certain conjunctival and corneal tumors and to decrease recurrence after pterygium excision. Caution is advocated when using mitomycin in light of the potentially serious delayed ocular complications.

**Agents Used in Ophthalmic Surgery**

**Presurgical Antiseptics**

Povidone iodine is formulated as a 5% sterile ophthalmic solution for use prior to surgery to prepare pericocular skin and irrigate ocular surfaces, including the cornea, conjunctiva, and palpebral fornices. Following irrigation, the exposed tissues are flushed with sterile saline. Hypersensitivity to iodine is a contraindication.

**Viscoelastic Substances**

The viscoelastic substances are agents that assist in ocular surgery by maintaining spaces, moving tissue, and protecting surfaces. These substances are prepared from hyaluronate, chondroitin sulfate, or hydroxypropylmethylcellulose and share varying degrees of the following important physical characteristics: viscosity, shear flow, elasticity, cohesiveness, and coatability. Complications associated with viscoelastic substances are related to transient elevation of IOP after surgery.

**Ophthalmic Glue**

Cyanacrylate tissue adhesive, while not FDA approved for the eye, is widely used in the management of corneal ulcerations and perforations.

Fibrin sealants are increasingly being used on the ocular surface to secure tissue such as conjunctiva, amniotic membrane, and lamellar corneal grafts.

**Anterior Segment Gases**

Sulfur hexafluoride (SF₆) and perfluoropropane gases are used as vitreous substitutes during retinal surgery. In the anterior segment, they are used in nonexpansile concentrations to treat Descemet’s detachments, typically after cataract surgery. These detachments can cause mild-to-severe corneal edema. The gas is injected into the anterior chamber to push Descemet’s membrane up against the stroma, where ideally it reattaches and clears the corneal edema. Similarly, these gases can be used after endothelial keratoplasty to help the lamellar graft adhere to the posterior cornea. SF₆ is an interesting molecule: octahedral geometry about the central S; a dense (6.1 g/mL) gas; odorless and nonflammable; industrial use; and a potent greenhouse gas with a long atmospheric t<sub>1/2</sub>.

**Vitreous Substitutes**

Several compounds, including gases, perfluorocarbon liquids, and silicone oils, are available as vitreous substitutes (Table 69–13; see details of mechanism in Chapter 66). Their primary use is reattachment of the retina following vitrectomy and membrane-peeling procedures for complicated proliferative vitreoretinopathy and traction retinal detachments. The use of expansile gases carries the risk of complications from elevated IOP, subretinal gas, corneal edema, and cataract formation. The gases are absorbed over a period of days (for air) to 2 months (for perfluoropropane).

The liquid perfluorocarbons (specific gravity 1.76–1.94) are denser than vitreous and are helpful in flattening the retina when vitreous is present. Silicone oil (polydimethylsiloxanes) is used for long-term tamponade of the retina. Complications from silicone oil use include glaucoma, cataract formation, corneal edema, corneal band keratopathy, and retinal toxicity.

**Surgical Hemostasis and Thrombolytic Agents**

Hemostasis has an important role in most surgical procedures and usually is achieved by temperature-mediated coagulation. Intravitreal administration of thrombin can assist in controlling intraocular hemorrhage during vitrectomy. When used intraocularly, a potentially significant inflammatory response may occur that can be minimized by thorough irrigation after hemostasis is achieved.

During intraocular surgeries to assist evacuation of a hyphema, subretinal clot, or nonclearing vitreous hemorrhage, tPA (Chapter 27) has been used off label. tPA also has been administered subconjunctivally and intracameraly (i.e., controlled intraocular administration into the anterior segment) to lyse blood clots obstructing a glaucoma filtration site. The main complication related to the use of tPA is bleeding.

cs, centistoke (unit of viscosity).

There are several medications that can cause central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage but generally will prevent further toxicity. Tamoxifen can cause crystalline maculopathy. The antiseizure drug vigabatrin causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients.

Optic Nerve
The PDE5 inhibitors sildenafil, vardenafil, and tadalaft inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection (Chapter 45) and to treat pulmonary arterial hypertension (Chapter 31). The drugs also mildly inhibit PDE6, which controls the levels of cyclic GMP in the retina (see Figure 69–9), causing a bluish haze or light sensitivity. Multiple medications, including ethambutol, chloramphenicol, and rifampin, can cause toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, are often required.

Anterior Segment
Steroids have been implicated in cataract formation. Tamoxifen, among other drugs, has also been associated with cataracts. Rifabutin, if used in conjunction with clarithromycin or fluconazole for treatment of *Mycobacterium avium* complex opportunistic infections in HIV-positive persons, is associated with an iridocyclitis and even hypopyon. These conditions resolve with steroids or by stopping the medication.

Ocular Surface
Isotretinoin has a drying effect on mucous membranes and is associated with dry eye and severe dysfunction of the meibomian gland.

Cornea, Conjunctiva, and Eyelids
The cornea, conjunctiva, and eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed *cornea verticillata*, appearing as fine tan or brown pigment in the epithelium. The deposits seldom affect vision and are rarely a cause to discontinue the medication. The deposits disappear slowly when the medication is stopped. Other medications, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine, can cause a similar pattern. The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmented deposits in the cornea, conjunctiva, and eyelids. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen. Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone. Certain chemotherapeutic agents, such as cytarabine, can cause temporary corneal toxicity.

Agents Used to Assist in Ocular Diagnosis
A number of agents are used in an ocular examination (e.g., mydriatic and local anesthetics); and to help in making a diagnosis in cases of anisocoria and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed previously. The diagnostic and local anesthetics are used in evaluating these conditions.

IOP and Glaucoma
The antiseizure drug topiramate can cause choroidal effusions leading to angle-closure glaucoma.

Retina
Numerous drugs have toxic side effects on the retina. The antiarthritics and antimalarial medicines hydroxychloroquine and chloroquine can cause central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage but generally will prevent further toxicity. Tamoxifen can cause crystalline maculopathy. The antiseizure drug vigabatrin causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients.

**Botulinum Toxin Type A in the Treatment of Strabismus, Blepharospasm, and Related Disorders**
Two botulinum toxin type A preparations are marketed in the U.S.: onabotulinumtoxinA and abobotulinumtoxinA. OnabotulinumtoxinA is FDA approved for the treatment of strabismus and blepharospasm associated with dystonia, facial wrinkles (glabellar lines), bladder dysfunction and urinary incontinence, upper limb spasticity, axillary hyperhidrosis, spasmodic torticollis (cervical dystonia), and chronic migraine. By preventing acetylcholine release at the neuromuscular junction, botulinum toxin A usually causes a temporary paralysis of the locally injected muscles. Complications related to this toxin include double vision (diplopia), eyelid droop (ptosis), and, rarely, potentially life-threatening distant spread of toxin effect from the injection site (hours to weeks after administration).

**Agents Used to Treat Blind and Painful Eye**
Retrobulbar injection of either absolute or 95% ethanol may provide relief from chronic pain associated with a blind and painful eye. Retrobulbar chlorpromazine also has been used off label. This treatment is preceded by administration of local anesthesia. Local infiltration of the ciliary nerves provides symptomatic relief from pain, but other nerve fibers may be damaged, causing paralysis of the extracocular muscles, including those in the eyelids, or neuromarphytic keratitis. The sensory fibers of the ciliary nerves may regenerate, and repeated injections sometimes are needed to control pain.

**Ocular Side Effects of Systemic Agents**
 Certain systemic drugs have ocular side effects. These can range from mild and inconsequential to severe and vision threatening (Li et al., 2008; Pula et al., 2013). Examples are listed in the sections that follow.

**IOP and Glaucoma**
The antiseizure drug topiramate can cause choroidal effusions leading to angle-closure glaucoma.

**Retina**
Numerous drugs have toxic side effects on the retina. The antiarthritics and antimalarial medicines hydroxychloroquine and chloroquine can cause central retinal toxicity by an unknown mechanism. With normal dosages, toxicity does not appear until about 6 years after the drug is started. Stopping the drug will not reverse the damage but generally will prevent further toxicity. Tamoxifen can cause crystalline maculopathy. The antiseizure drug vigabatrin causes progressive and permanent bilateral concentric visual field constriction in a high percentage of patients.

**Optic Nerve**
The PDE5 inhibitors sildenafil, vardenafil, and tadalaft inhibit PDE5 in the corpus cavernosum to help achieve and maintain penile erection (Chapter 45) and to treat pulmonary arterial hypertension (Chapter 31). The drugs also mildly inhibit PDE6, which controls the levels of cyclic GMP in the retina (see Figure 69–9), causing a bluish haze or light sensitivity. Multiple medications, including ethambutol, chloramphenicol, and rifampin, can cause toxic optic neuropathy characterized by gradually progressive bilateral central scotomas and vision loss. Systemic or ocular steroids can cause elevated IOP and glaucoma. If the steroids cannot be stopped, glaucoma medications, and even filtering surgery, are often required.

**Anterior Segment**
Steroids have been implicated in cataract formation. Tamoxifen, among other drugs, has also been associated with cataracts. Rifabutin, if used in conjunction with clarithromycin or fluconazole for treatment of *Mycobacterium avium* complex opportunistic infections in HIV-positive persons, is associated with an iridocyclitis and even hypopyon. These conditions resolve with steroids or by stopping the medication.

**Ocular Surface**
Isotretinoin has a drying effect on mucous membranes and is associated with dry eye and severe dysfunction of the meibomian gland.

**Cornea, Conjunctiva, and Eyelids**
The cornea, conjunctiva, and eyelids can be affected by systemic medications. One of the most common drug deposits found in the cornea is from the cardiac medication amiodarone. It deposits in the inferior and central cornea in a whorl-like pattern termed *cornea verticillata*, appearing as fine tan or brown pigment in the epithelium. The deposits seldom affect vision and are rarely a cause to discontinue the medication. The deposits disappear slowly when the medication is stopped. Other medications, including indomethacin, atovaquone, chloroquine, and hydroxychloroquine, can cause a similar pattern. The phenothiazines, including chlorpromazine and thioridazine, can cause brown pigmented deposits in the cornea, conjunctiva, and eyelids. They typically do not affect vision. The ocular deposits generally persist after discontinuation of the medication and can even worsen. Tetracyclines can cause a yellow discoloration of the light-exposed conjunctiva. Systemic minocycline can induce a blue-gray scleral pigmentation that is most prominent in the interpalpebral zone. Certain chemotherapeutic agents, such as cytarabine, can cause temporary corneal toxicity.

**Agents Used to Assist in Ocular Diagnosis**
A number of agents are used in an ocular examination (e.g., mydriatic agents, topical anesthetics, dyes to evaluate corneal surface integrity); to facilitate intraocular surgery (e.g., mydriatic and miotic agents, topical and local anesthetics); and to help in making a diagnosis in cases of anisocoria and retinal abnormalities (e.g., intravenous contrast agents). The autonomic agents have been discussed previously. The diagnostic and therapeutic uses of topical and intravenous dyes and of topical anesthetics are discussed in the material that follows.

**Anterior Segment and External Diagnostic Uses**
Epiphora (excessive tearing) and surface problems of the cornea and conjunctiva are commonly encountered external ocular disorders. The dyes fluorescein, rose bengal, and lissamine green are used in evaluating these problems. Fluorescein (Figure 69–7; available as 10% and 25% solutions for injection and as an impregnated paper strip) reveals epithelial defects of the cornea and conjunctiva and aqueous humor leakage that may occur after trauma or ocular surgery. In the setting of epiphora, fluorescein is used to determine the patency of the nasolacrimal system. In addition, this dye is used in *applanation tonometry* (IOP measurement) and to assist...
in determining the proper fit of rigid and semirigid contact lenses. Fluorescein in combination with proparacaine or benoxinate is available for procedures in which a disclosing agent is needed in conjunction with a topical anesthetic. Fluorescein, a high-molecular-weight fluorescent solution, is used when fluorescein is contraindicated (as when soft contact lenses are in place). Rose bengal and lissamine green (available as saturated paper strips) stain devitalized tissue on the cornea and conjunctiva.

**Posterior Segment Diagnostic Uses**
The integrity of the blood-retinal and retinal pigment epithelial barriers may be examined directly by retinal angiography using intravenous administration of either fluorescein sodium or indocyanine green. These agents commonly cause nausea and may precipitate serious allergic reactions in susceptible individuals.

**Treatment of Retinal Neovascularization, Macular Degeneration, and Vitreomacular Traction**
The medical treatment of retinal neovascularization has been changing rapidly in the past several years and will likely continue to do so (Agarwal et al., 2015). Current treatment employs agents that inhibit the actions of VEGF (Table 69–14).

**Verteporfin** is approved for photodynamic therapy of the exudative form of ARM with predominantly classic choroidal neovascular membranes. Verteporfin also is used in the treatment of predominantly classic choroidal neovascularization caused by conditions such as pathological myopia and presumed ocular histoplasmosis syndrome. Verteporfin is administered intravenously; once it reaches the choroidal circulation, the drug is light activated by a nonthermal laser source. Activation of the drug in the presence of O₂ generates free radicals, which cause vessel damage and subsequent platelet activation, thrombosis, and occlusion of choroidal neovascularization. The t½ of the drug is 5–6 h; it is eliminated predominantly in the feces. Potential side effects include headache, injection site reactions, and visual disturbances. The drug causes temporary photosensitization; patients must avoid exposure of the skin or eyes to direct sunlight or bright indoor lights for 5 days after receiving verteporfin.

**Pegaptanib**, a selective VEGF antagonist, is approved for neovascular (wet) ARM. VEGF₁₆₅ induces angiogenesis and increases vascular permeability and inflammation, which actions likely contribute to the progression of the neovascular (wet) form of ARM, a leading cause of blindness. Pegaptanib inhibits VEGF₁₆₅ binding to VEGF receptors. Pegaptanib (0.3 mg) is administered once every 6 weeks by intravitreal injection into the eye to be treated. Following the injection, patients should be monitored for elevation in IOP and for endophthalmitis. Rare cases of anaphylaxis/anaphylactoid reactions have been reported.

**Afiblercept** is a recombinant fusion protein, consisting of portions of human VEGF receptors 1 and 2, that acts as a soluble decoy receptor for VEGF–A. It is approved for the neovascular (wet) form of ARM as well as macular edema following retinal vein occlusion or associated with diabetic retinopathy. Depending on the underlying disease, afiblercept (2 mg) is administered once every month by intravitreal injection into the eye for 3–5 months, followed by 2 mg once every 8 weeks. Serious side effects may include eye pain or redness, swelling, vision problems, photosensitivity, headaches, sudden numbness on one side of the body, confusion, and problems with speech and balance. The drug is contraindicated in patients who have an active eye infection or active ocular inflammation.

**Bevacizumab** is a monoclonal murine antibody that targets VEGF–A and thereby inhibits vascular proliferation and tumor growth (see Chapter 67). Intraocular use is considered off label but is routinely done. **Ranibizumab** is a variant of bevacizumab that has had the Fab domain affinity matured. Both drugs are delivered by intravitreal injection and often are used on a weekly or monthly basis for maintenance therapy. Both have been associated with the risk of cerebral vascular accidents. The enormous cost difference between these similar antibodies has sparked a debate about the cost-effectiveness of treatment strategies (Shaikh et al., 2015; Stein et al., 2014), especially in light of recent data indicating similar visual acuity outcomes for each medicine (CATT Research Group, 2011).

**Ocriplasmin** is a proteolytic enzyme that is used to treat vitreomacular traction. It works to dissolve the vitreous and relieve traction on the macula in the center of the retina. An interesting side effect is the possibility of lens subluxation from zonular dehiscence.

**Anesthetics in Ophthalmic Procedures**
Topical anesthetic agents used clinically in ophthalmology include proparacaine and tetracaine drops, lidocaine gel (see Chapter 22), and intra-nasal cocaine. Cocaine may be used intranasally in combination with topical anesthesia for cannulating the nasolacrimal system. Lidocaine and

bupivacaine are used for infiltration and retrobulbar block anesthesia for surgery. Potential complications and risks relate to allergic reactions, globe perforation, hemorrhage, and vascular and subdural injections. Both preservative-free lidocaine (1%), which is introduced into the anterior chamber, and lidocaine jelly (2%), which is placed on the ocular surface during preoperative patient preparation, are used for cataract surgery performed under topical anesthesia. Most inhalational agents and CNS depressants are associated with a reduction in IOP. An exception is ketamine, which has been associated with an elevation in IOP. In the setting of a patient with a ruptured globe, the anesthesia should be selected carefully to avoid agents that depolarize the extraocular muscles, which may result in expulsion of intraocular contents.

### Wetting Agents, Tear Substitutes, Osmotic Agents

The current management of dry eyes usually includes instilling artificial tears and other ophthalmic lubricants. In general, tear substitutes are hypotonic or isotonic solutions composed of electrolytes, surfactants, preservatives, and some viscosity-increasing agent that prolongs the residence time in the cul-de-sac and precorneal tear film. Common viscosity agents include cellulose polymers, polyvinyl alcohol, polyethylene glycol, polysorbate, mineral oil, glycerin, and dextran. The tear substitutes are available as preservative-containing or preservative-free preparations. The viscosity of the tear substitute depends on its exact formulation and can range from watery to gel like. Some tear formulations also are combined with a vasoconstrictor, such as naphazoline, phenylephrine, or tetrahydrozoline. The lubricating ointments are composed of a mixture of white petrolatum, mineral oil, liquid or alcohol lanolin, and sometimes a preservative. These highly viscous formulations cause considerable blurring of vision; consequently, they are used primarily at bedtime, in critically ill patients, or in very severe dry eye conditions. A hydroxypropyl cellulose ophthalmic insert that is placed in the inferior cul-de-sac and dissolves during the day is available to treat dry eyes.

Local eye disease, such as blepharitis, ocular rosacea, ocular pemphigoid, chemical burns, or corneal dystrophies, may alter the ocular surface and change the tear composition. Appropriate treatment of the symptomatic dry eye includes treating the accompanying disease and possibly the addition of tear substitutes, punctal plugs (see Absorption), or ophthalmic cyclosporine (see Immunosuppressants). There also are a number of systemic conditions that may manifest themselves with symptomatic dry eyes, including Sjögren syndrome, rheumatoid arthritis, vitamin A deficiency, Stevens-Johnson syndrome, and trachoma. Treating the systemic disease may not eliminate the symptomatic dry eye complaints; chronic therapy with tear substitutes, ophthalmic cyclosporine, insertion of punctal plugs, placement of dissolvable collagen implants, or surgical occlusion of the lacrimal drainage system may be indicated. Ophthalmic cyclosporine can be used to increase tear production in patients with ocular inflammation associated with keratoconjunctivitis sicca.

The main osmotic drugs for ocular use are glycerin, mannitol, and hypertonic saline. Glycerin and mannitol are used for short-term management of acute rises in IOP. Sporadically, these agents are used intraoperatively to dehydrate the vitreous prior to anterior segment surgical procedures. Many patients with acute glaucoma do not tolerate oral medications because of nausea; therefore, intravenous administration of mannitol or acetazolamide may be preferred over oral administration of glycerin. These agents should be used with caution in patients with congestive heart failure or renal failure.

Corneal edema is a clinical sign of corneal endothelial dysfunction, and topical osmotic agents may effectively dehydrate the cornea. NaCl is available in either aqueous or ointment formulations. Topical glycerin also is available; however, because it causes pain on contact with the cornea and conjunctiva, its use is limited to urgent evaluation of filtration-angle structures. In general, when corneal edema occurs secondary to acute glaucoma, the use of an oral osmotic agent to help reduce IOP is preferred over topical glycerin, which simply clears the cornea temporarily. Reducing the IOP will help clear the cornea more permanently to allow both a view of the filtration angle by gonioscopy and a clear view of the iris as required to perform laser iridotomy.

### Vitamin A and the Visual Cycle

Vitamin deficiencies can alter eye function, especially a deficiency of vitamin A (Table 69–15). In vision, the functional form of vitamin A is retinal; its deficiency interferes with vision in dim light, contributing to a condition known as night blindness (nyctalopia).

### Chemistry

Retinoid refers to the chemical entity retinol and other closely related naturally occurring derivatives. Retinoids, which exert most of their effects by binding to specific nuclear receptors and modulating gene expression, also include structurally related synthetic analogues that need not have retinol-like (vitamin A) activity. The purified plant pigment carotene (provitamin A) is a proenome source of vitamin A. β-Carotene is the most active
carotenoid found in plants. The structural formulas for β-carotene and the vitamin A family of retinoids are shown in Figure 69–8. Retinoic acid analogues used clinically are discussed in detail in Chapter 70.

Retinal Cells and the Visual Cycle
Photoreception is accomplished by two types of specialized retinal cells, rods and cones. Rods are especially sensitive to light of low intensity; cones act as receptors of high-intensity light and are responsible for color vision. The chromophore of both rods and cones is 11-cis-retinal. The holoreceptor in rods is termed rhodopsin—a combination of the protein opsin and 11-cis-retinal attached as a prosthetic group. The three different types of cone cells (red, green, and blue) contain individual, related, photoreceptor proteins and respond optimally to light of different wavelengths. Several review articles summarized the process of photoreception (Kefalov, 2012; Saari, 2016). Figure 69–9 summarizes the signaling pathway initiated by absorption of a photon by 11-cis-retinal in rods.

Vitamin A Deficiency
Vitamin A is an essential nutrient with multiple functions in the body, including the eye (Sommer and Vyas, 2012). Humans deficient in vitamin A lose their ability for dark adaptation. Rod vision is affected more than cone vision. On depletion of retinol from liver and blood, usually at plasma concentrations of retinol of less than 0.2 mg/L (0.70 μM), the concentrations of retinol and rhodopsin in the retina fall. Unless the deficiency
is overcome, opsin, lacking the stabilizing effect of retinal, decays, and anatomical deterioration of the rod outer segment occurs.

**Vitamin A and Epithelial Structures**

In the presence of retinol or retinoic acid, basal epithelial cells are stimulated to produce mucus. Excessive concentrations of the retinoids lead to the production of a thick layer of mucus, the inhibition of keratinization, and the display of goblet cells. In the absence of vitamin A, goblet mucous cells disappear and are replaced by basal cells that have been stimulated to proliferate. These undermine and replace the original epithelium with a stratified, keratinizing epithelium. The suppression of normal secretions leads to irritation and infection. Reversal of these changes is achieved by the administration of retinol, retinoic acid, or other retinoids. When this process happens in the cornea, severe hyperkeratinization (xerophthalmia) may lead to permanent blindness (McLaren and Kraemer, 2012). Common causes of vitamin A deficiency include malnutrition and bariatric surgery.

Retinoic acid influences gene expression by combining with nuclear receptors (see Figures 3–12 and 6–8). There are two families of retinoid receptors: the RARs and the RXRs. The endogenous RXR ligand is 9-cis-retinoic acid.

**Therapeutic Uses of Vitamin A**

Nutritional vitamin A deficiency causes xerophthalmia, a progressive disease characterized by nyctalopia (night blindness), xerosis (dryness), and keratomalacia (corneal thinning), which may lead to corneal perforation. Vitamin A therapy can reverse xerophthalmia; however, rapid, irreversible blindness ensues once the cornea perforates. Vitamin A also is involved in epithelial differentiation and may have a role in corneal epithelial wound healing. The current recommendation for retinitis pigmentosa is to administer 15,000 IU of vitamin A palmitate daily under the supervision of an ophthalmologist and to avoid high-dose vitamin E.

Chapter 70 Dermatological Pharmacology
Matthew J. Sewell, Craig N. Burkhart, and Dean S. Morrell

Principles of Dermatological Pharmacology

The skin is a biologically active, multifunctional, and multicompartment organ. Medications can be applied to the skin for two purposes: to directly treat disorders of the skin and to deliver drugs to other tissues. Effective and safe use of topical pharmacological therapies requires an understanding of skin physiology and factors influencing percutaneous drug absorption and metabolism (Hwa et al., 2011; Wolff et al., 2008). General features of skin structure and percutaneous absorption pathways are outlined in Figure 70–1.

Nonpharmacological therapy is also used for treatment of skin diseases. This includes the use of parts of the electromagnetic spectrum applied by various sources, such as lasers, X-rays, visible light, and infrared light. These approaches may be used alone or to enhance the penetration or alter the nature of drugs and prodrugs. Freezing and ultrasound are other physical therapies that alter epidermal structure for direct treatment or to enhance percutaneous absorption of drugs. Chemicals are also used to decrease the effect of various wavelengths of UV light and ionizing radiation on the skin.

Structure of Skin

Stratum Corneum

The stratum corneum is the major barrier to percutaneous absorption of drugs and to the loss of water from the body. It may be considered the “nonliving” portion of the epidermis. The stratum corneum differs in thickness at different body sites, with the palm and sole the thickest followed by the general body stratum corneum, facial and postauricular area, and the eyelid and scrotum.

A drug may partition into the stratum corneum and form a reservoir that will diffuse into the rest of skin even after topical application of the drug has ceased.

Living Epidermis

The living layers of the epidermis (stratum basale, stratum spinosum, and stratum granulosum) with metabolically active cells comprise a layer about 100 μm thick (Figure 70–1). Intercalated in the living epidermis are pigment-producing cells (melanocytes), neuroendocrine cells (Merkel cells), dendritic APCs (Langerhans cells), and other immune cells (γ-δ T cells). In diseased epidermis, many additional immunological cells, including lymphocytes and polymorphonuclear leukocytes, may be present and be directly affected by applied drugs.

Dermis and Its Blood Vessels

The dermis provides mechanical strength and flexibility to the skin. It is composed primarily of fibroblasts and an extracellular matrix, including collagen, proteoglycans, glycoproteins, and, in the upper dermis, elastic fibers. Cells within the dermis that may be targets for drugs include mast cells (permanent residents and producers of many inflammatory
mediators) and infiltrating immune cells producing cytokines. The dermis also contains networks of nerves, blood vessels, and adnexal structures. The superficial capillary plexus between the epidermis and dermis is the site of the majority of the systemic absorption of cutaneous drugs (see Figure 70–1). There are large numbers of lymphatics as well. Hair follicles form a lipid-rich pathway for drug absorption but only constitute 0.1% of the total skin area, so this is not the primary route of absorption. Sweat glands are not known as a pathway for the absorption of drugs, but some drugs (e.g., griseofulvin) are excreted to the skin by this route. Below the dermis is the hypodermis or subcutaneous tissue, which provides insulating, cushioning, and an energy reservoir.

**Mechanisms of Percutaneous Absorption**

Percutaneous absorption occurs primarily through a tortuous intercellular route, with transcellular or appendageal routes playing a much smaller role. Passage through the stratum corneum is the rate-limiting step for percutaneous absorption. Preferable characteristics of topical drugs include:

- low molecular mass (≤500 Da);
- adequate solubility in both oil and water; and
- a high partition coefficient so the drug will selectively partition from the vehicle to the stratum corneum (Hwa et al., 2011; Tran, 2013).

Except for very small particles, water-soluble ions and polar molecules do not penetrate significantly through intact stratum corneum. The exact amount of drug entering or leaving the skin in clinical situations usually is not measured; rather, the clinical end point (e.g., reduction in inflammation) usually is the desired effect.

A hydrated stratum corneum allows more percutaneous absorption and often is achieved through the selection of drugs formulated in occlusive vehicles such as ointments and the use of plastic films, wraps, or bags for the hands and feet and shower or bathing caps for the scalp. Alternatively, medications that are impregnated on patches or tapes may be used. Occlusion may be associated with increased growth of bacteria and resultant infection (folliculitis) or maceration and breakdown of the epidermis. Absorption of most drugs across the skin is a passive process; heat generally increases penetration. Ultrasonic energy, electric currents (iontophoresis), minimally invasive microneedling, and fractional or ablative lasers also can be used to increase percutaneous absorption (Tran, 2013).

Transdermal drug delivery bypasses hepatic first-pass metabolism; however, the epidermis contains a variety of enzyme systems capable of metabolizing drugs that reach this compartment. A specific CYP isoenzyme, CYP26A1, metabolizes retinoic acid and may control its level in the skin (Baron et al., 2001). In addition, transporter proteins that influence influx (OATP) or efflux (MDR [multidrug resistance transporter], P-glycoprotein) of certain xenobiotics are present in human keratinocytes (Baron et al., 2001). Genetic variants of enzymes that regulate the cellular influx and efflux of methotrexate have been associated with toxicity and effectiveness in patients with psoriasis (Warren et al., 2008).

**Pharmacologic Implications of Epidermal Structure**

When proposing topical application of medications, the healthcare provider must consider multiple factors, including proper dosage and frequency of application, extent and condition of the permeability barrier, patient age and weight, physical form of the preparation to be applied, and whether intralesional or systemic administration should be used (Table 70–1). Various drug vehicles have specific advantages and disadvantages (Table 70–2). Newer vehicles, such as liposomes and micрогel formulations, can enhance solubilization of certain drugs, thereby enhancing topical penetration and diminishing irritancy (Rosen et al., 2014). Children have a greater ratio of surface area to mass than adults do, so the same amount of topical drug can result in greater systemic exposure. Premature infants have a marked impaired barrier function until the epidermis keratinizes completely (Hwa et al., 2011). Many dermatological diseases also compromise barrier function, leading to increased percutaneous absorption.

**Glucocorticoids**

Glucocorticoids have immunosuppressive and anti-inflammatory properties. They are administered locally through topical and intralesional routes and systematically through intramuscular, intravenous, and oral routes. Mechanisms of glucocorticoid action are discussed in Chapter 46.
Topical Glucocorticoids

Topical glucocorticoids have been grouped into seven classes in order of decreasing potency (Table 70–3). Potency traditionally is measured using a vasoconstrictor assay in which an agent is applied to skin under occlusion, and the area of skin blanching is assessed. Other assays of glucocorticoid potency involve suppression of erythema and edema after experimentally induced inflammation and the psoriasis bioassay, in which the effect of steroid on psoriatic lesions is quantified.

Therapeutic Uses

Many inflammatory skin diseases respond to topical or intralesional administration of glucocorticoids. Absorption varies amongst body sites and with the vehicle of the formulation. The steroid is selected on the basis of its potency, the site of involvement, and the severity of the skin disease. Often, a more potent steroid is used initially, followed by a less potent agent. Twice-daily application of topical glucocorticoids suffices; more frequent application does not improve response. Moderately potent to very potent topical corticosteroids are effective with once-daily versus twice-daily application in atopic dermatitis, and patient adherence may be improved with once-daily regimens (Williams, 2007). In general, only nonfluorinated glucocorticoids should be used on the face or in occluded areas such as the axillae or groin. Intraleisional preparations of glucocorticoids include insoluble preparations of triamcinolone acetonide and triamcinolone hexacetonide, which solubilize gradually and therefore have a prolonged duration of action.

Toxicity

Chronic use of class 1 topical glucocorticoids can cause skin atrophy, striae, telangiectasias, purpura, and acneiform eruptions. Because perioral
dermatitis and rosacea can develop after the use of fluorinated compounds on the face, they should not be used on this site. Occlusion increases the risk of HPA axis suppression.

Systemic Glucocorticoids

Systemic glucocorticoid therapy is used for severe dermatological illnesses and generally is reserved for allergic contact dermatitis to plants (e.g., poison ivy) and for life-threatening vesiculobullous dermatoses such as pemphigus vulgaris and bullous pemphigoid. Chronic administration of oral glucocorticoids is problematic, given the side effects associated with their long-term use (see Chapter 46).

Daily morning dosing with prednisone generally is preferred, although divided doses occasionally are used to enhance efficacy. Fewer side effects are seen with alternate-day dosing; if chronic therapy is required, prednisone usually is tapered to every other day as soon as practical. Pulse therapy using large intravenous doses of methylprednisolone sodium succinate is an option for severe resistant pyoderma gangrenosum, pemphigus vulgaris, systemic lupus erythematosus with multisystem disease, and dermatomyositis. The dose of intravenous methylprednisolone usually is 0.5–1 g given over 2–3 h. More rapid infusion has been associated with increased rates of hypotension, electrolyte shifts, and cardiac arrhythmias.

Toxicity and Monitoring

Oral glucocorticoids have numerous systemic effects, as discussed in Chapter 46. Most side effects are dose dependent.

### Retinoids

Retinoids comprise natural and synthetic compounds that exhibit vitamin A–like biological activity or bind to nuclear receptors for retinoids. Characteristics of topical and systemic retinoids are summarized in Tables 70–4 and 70–5, respectively.

First-generation retinoids include retinol (vitamin A), tretinoin (all-trans-retinoic acid; vitamin A acid), isotretinoin (13-cis-retinoic acid), and alitretinoin (9-cis-retinoic acid). Second-generation retinoids, also known as aromatic retinoids, include acitretin. Third-generation retinoids were designed to optimize receptor-selective binding and include tazarotene, bexarotene, and adapalene.

- **Mechanism of Action.** Retinoids exert their effects on gene expression by activating two families of receptors, RARs and RXRs, which are members of the steroid receptor superfamily. Both retinoid receptor families have three isoforms (α, β, and γ), which are expressed in unique combinations in individual tissues and cells. On binding to a retinoid, RARs and RXRs form heterodimers (RAR-RXR) that subsequently bind specific DNA sequences called RAREs that activate transcription of genes whose products produce both the desirable pharmacological effects and the unwanted side effects of these drugs (see Tables 6–5, 70–4 and 70–5, and Figure 6–13).

  - **Targeted Therapeutic Actions.** Retinoids that target RARs predominantly affect cellular differentiation and proliferation, whereas retinoids that target RXRs predominantly induce apoptosis. Hence, tretinoin, adapalene, and tazarotene, which target RARs, are used in acne, psoriasis, and photodaging (disorders of differentiation and proliferation), whereas bexarotene and alitretinoin, which target RXRs, are used in CTCL and Kaposi sarcoma, respectively, to induce apoptosis of malignant cells.

  - **Retinoid Toxicity.** Acute retinoid toxicity is similar to vitamin A intoxication. Side effects of systemic retinoids include dry skin, nosebleeds from dry mucous membranes, conjunctivitis, reduced night vision, hair loss, alterations in serum lipids and transaminases, hypothyroidism, inflammatory bowel disease flare, musculoskeletal pain, pseudotumor cerebri, and mood alterations. RAR-selective retinoids are more associated with mucocutaneous and musculoskeletal symptoms, whereas RXR-selective retinoids induce more physiological changes. Because all oral retinoids are potent teratogens, they should be used carefully in females of childbearing potential and not in pregnant patients.

Topical Retinoids

Through incompletely understood mechanisms, topical retinoids correct abnormal follicular keratinization, reduce Propionibacterium acnes counts, and reduce inflammation, thereby making them the cornerstone of acne therapy. Topical retinoids are first-line agents for noninflammatory (comedonal) acne and often are combined with other agents in the management of inflammatory acne.

Fine wrinkles and dyspigmentation, two important features of photoaging, are also improved with topical retinoids. Within the dermis, this is believed to result from inhibition of AP-1, which normally activates synthesis of matrix metalloproteinases in response to UV irradiation (Thielitz and Gollnick, 2008). In the epidermis, retinoids induce epidermal hyperplasia in atrophic skin and reduce keratinocyte atypia.

**Toxicity and Monitoring**

Adverse effects of all topical retinoids include erythema, desquamation, burning, and stinging (see relative irritancy in Table 70–4). These effects often decrease with time and are lessened by concomitant use of emollients. Patients may also experience photosensitivity reactions (enhanced reactivity to UV radiation) and have a significant risk for severe sunburn. Although there is little systemic absorption of topical retinoids and no alteration in plasma vitamin A levels with their use, topical retinoids are not recommended for use during pregnancy.

**Available Agents; Clinical Use**

**Tretinoin** (all-trans-retinoic acid) is photo tolerable and should be applied once nightly for acne and photodaging. Benzoyl peroxide also inactivates tretinoin to decrease irritancy are available and are less susceptible to oxidation by benzoyl peroxide and photodegradation.

**Adapalene** has similar efficacy to tretinoin, but unlike tretinoin, it is stable in sunlight or the presence of benzoyl peroxide and tends to be less irritating.

**Tazarotene** is approved for the treatment of psoriasis, photodaging, facial wrinkles, and acne vulgaris. Tazarotene gel, applied once daily, may be used as monotherapy or in combination with other medications, such as topical corticosteroids, for the treatment of localized plaque psoriasis. Topical corticosteroids improve the efficacy of therapy and reduce the side effects of burning, itching, and skin irritation that are commonly associated with tazarotene.

**Alitretinoin** is a retinoid that binds all types of retinoid receptors, both RARs and RXRs. It is approved for treatment of cutaneous lesions...
of Kaposi sarcoma, with its application titrated up from twice daily to three or four times daily as tolerated. Alltransretinoic acid should not be applied concurrently with insect repellants containing diethyltoluamide (DEET) because it may increase DEET absorption. Bexarotene is approved for early-stage (IA and IB) CTCL. Its application is titrated up from every other day to two to four times daily over several weeks to improve patient tolerance. Concurrent application of bexarotene with insect repellants containing DEET is not recommended because it may increase DEET absorption.

Systemic Retinoids

Systemic retinoids (Table 70–5) are approved for the treatment of acne, psoriasis, and CTCL (Desai et al., 2007).

**Therapeutic Uses and Contraindications**

Off-label uses include ichthyosis, Darier disease, pityriasis rubra pilaris, rosacea, hidradenitis suppurativa, chemoprevention of malignancy, lichen sclerosis, subacute lupus erythematosus, and discoid lupus erythematosus. Absolute contraindications include use by women who are pregnant, planning to become pregnant, or breastfeeding. Relative contraindications include leukopenia, alcoholism, hyperlipidemia, hypercholesterolemia, hypothyroidism, and significant hepatic or renal disease.

**Toxicity and Monitoring**

Acute toxicities may include mucocutaneous or laboratory abnormalities; bony changes may occur after chronic use at high doses. Mucocutaneous side effects may include chilblain, xerosis, blepharoconjunctivitis, cutaneous photosensitivity, photophobia, myalgia, arthralgia, headaches, alopecia, nail fragility, and increased susceptibility to staphylococcal infections. Some patients develop a “retinoid dermatitis” characterized by erythema, pruritus, and scaling. Very rarely, patients may develop pseudotumor cerebri, especially when systemic retinoids are combined with tetracyclines. There are reports that chronic administration at higher doses can cause diffuse idiopathic skeletal hyperostosis (DISH) syndrome, premature epiphyseal closure, and other skeletal abnormalities (Desai et al., 2007).

Systemic retinoids are highly teratogenic. There is no safe dose during pregnancy. Prescribing of isotretinoin in the U.S. is restricted via the risk-mitigation iPLEDGE system.

Serum lipid elevation is the most common laboratory abnormality. Less common laboratory abnormalities include elevated transaminases, decreased thyroid hormone, and leukopenia. A baseline evaluation of serum lipids, serum transaminases, and CBC should be obtained prior to starting any systemic retinoids. These laboratory values are usually subsequently checked monthly for the first 3–6 months and once every 3 months thereafter. In addition, two negative pregnancy tests on separate occasions are required for females of childbearing potential prior to starting acitretin or isotretinoin; bexarotene requires one negative pregnancy test within the week prior to initiating therapy. Monthly pregnancy tests should be obtained for females of childbearing potential.

**Available Agents and Clinical Use**

Isotretinoin is approved for the treatment of recalcitrant and nodular acne vulgaris. The drug has remarkable efficacy in severe acne and may induce prolonged remissions after a single course of therapy. Clinical effects generally are noted within 1–3 months of starting therapy. Approximately one-third of patients will relapse, usually within 3 years of stopping therapy. Although most relapses are mild and respond to conventional management with topical and systemic antiacne agents, some may require a second course of isotretinoin. Systemic absorption is improved when taken with a high-fat meal. An isotretinoin-Lidose formulation (a eutectic mixture of drug and lipids in a hard gelatin capsule) may be given without respect to meals.

Acitretin is approved for use in the cutaneous manifestations of psoriasis. Clinical effect may begin within 4–6 weeks, with the full clinical benefit occurring at 3–6 months. Acitretin has a t½ of about 50 h; however, when combined with alcohol, acitretin is esterified in vivo to produce etretinate, which has a t½ of more than 3 months. It is not known how much alcohol (i.e., cough syrup or other alcohol-based medications) is required to induce this conversion. Thus, female patients of childbearing potential should avoid pregnancy for 3 years after receiving acitretin to avoid retinoid-induced embryopathy.

Bexarotene is a retinoid that selectively binds RXRs. Oral and topical formulations of bexarotene are approved for use in patients with CTCL. Bexarotene reportedly induces apoptosis of malignant cells (Jawed et al., 2014). Because CYP3A4 metabolizes bexarotene, inhibitors of CYP3A4 (e.g., imidazole antifungals, macrolide antibiotics) will increase and inducers of CYP3A4 (e.g., rifamycins, carbamazepine, dexamethasone, efavirenz, phenobarbital) will decrease plasma levels of bexarotene. Side effects are more common than with other retinoids, with an increased incidence of significant lipid abnormalities and hypothyroidism secondary to a reversible RXR-mediated suppression of TSH gene expression, pancreatitis, leukopenia, and GI symptoms. Thyroid function should be measured before initiating therapy and periodically thereafter.

### Vitamin Analogues

#### Calcipotriene
Calcipotriene is a topical vitamin D analogue that is used in the treatment of psoriasis.

**Mechanism of Action**
Calcipotriene exerts its effects through the VDR (see Chapter 48). On binding the VDR, the drug-receptor complex associates with the RXR-α and binds to vitamin D response elements on DNA, increasing expression of genes that modulate epidermal differentiation and inflammation, leading to improvement in psoriatic plaques (Menter et al., 2009a).

**Therapeutic Use**
Calcipotriene is applied twice daily to plaque psoriasis on the body, often in combination with topical corticosteroids. Hypercalcemia and hypercalciuria may develop when the cumulative weekly dose exceeds the recommended 100 g/week limit and resolves within days of discontinuation of calcipotriene (Menter et al., 2009a). Calcipotriene also causes perilesional irritation and mild photosensitivity. Concomitant administration of topical corticosteroids will reduce the irritation. Calcipotriene has been used off label for multiple conditions, including morphea, vitiligo, and congenital ichthyoses.

#### β-Carotene
β-Carotene is a precursor of vitamin A that is in green and yellow vegetables. No β-carotene products are currently FDA approved. Dietary supplementation with β-carotene is used in dermatology to reduce skin photosensitivity in patients with erythropoietic protoporphyria. The mechanism of action is not established but may involve an antioxidant effect that decreases the production of free radicals or singlet oxygen. A meta-analysis concluded that β-carotene, vitamin A, and vitamin E, given singly or combined with other antioxidant supplements, did not provide any benefit in lowering mortality or decreasing the risk of cerebrovascular accident. In addition, use of β-carotene and vitamin E led to an increase in all-cause mortality (Bjelakovic et al., 2012). The FDA’s maximum recommended therapeutic dose (MRTD) for β-carotene is 0.05 mg/kg/d.

### Photochemotherapy

Phototherapy and photochemotherapy are treatment methods in which UV or visible radiation is used to induce a therapeutic response either alone (phototherapy) or in the presence of an exogenous photosensitizing drug (photochemotherapy) (Table 70–6). Patients treated with these modalities should be monitored for concomitant use of other potential photosensitizing medications, such as phenothiazines, thiazides, sulfonamides, NSAIDs, sulfonylureas, tetracyclines, and benzodiazepines.

CNS, central nervous system; CTCL, cutaneous T cell lymphoma; GI, gastrointestinal; HSV, herpes simplex virus; UVA, ultraviolet A.
The UV radiation region may be subdivided into UVA1 (340–400 nm), UVA2 (320–340 nm), UVB (290–320 nm), and UVC (100–290 nm). UVC radiation is almost completely absorbed by the ozone layer and atmosphere so that measurable amounts do not reach Earth’s surface. UVA and UVB exposure can cause sunburns, photoaging, and skin cancer. UVB is the most erythrogenic and melanogenic, and it is the major action spectrum for sunburn, tanning, skin cancer, photoaging, and cutaneous vitamin D synthesis. UVA is only a thousandth as erythrogenic as UVB but penetrates more deeply into the skin and contributes substantially to photoaging and photosensitivity diseases. UVA is also able to penetrate clouds and glass, so exposure may occur even in the shade or while indoors. Both UVA and UVB cause photoinhibitory suppression, an effect that is utilized for therapy of certain dermatological conditions.

**PUVA: Psoralsens and UVA**

The PUVA combines UVA light with photosensitizing compounds called psoralsens. Orally administered methoxsalen (8-methoxypsoralen) followed by UVA (PUVA) is FDA approved for the treatment of vitiligo and psoriasis. It is also used off-label in several other inflammatory or lymphoproliferative cutaneous disorders (Totonchy and Chiu, 2014).

**Chemistry and Mechanism of Action**

Psoralsens are lipophilic, naturally occurring furocumarins found in some plants. Synthetic versions are also available. The action spectrum for PUVA is between 320 and 340 nm. Psoralsens intercalate into the DNA strand, and two distinct photoreactions take place on UVA exposure. Type I reactions involve the oxygen-independent photoaddition of psoralsens to pyrimidine bases in DNA. Type II reactions are oxygen dependent and involve the transfer of energy to molecular oxygen, creating reactive oxygen species. Through incompletely understood mechanisms, these phototoxic reactions stimulate melanocytes and induce antiproliferative, immunosuppressive, and anti-inflammatory effects.

**Pharmacokinetics**

Formulations of solubilized methoxsalen in a gel matrix are rapidly absorbed by oral administration, whereas older microcrystalline forms are absorbed slowly and incompletely. Fatty foods slow absorption and decrease peak blood levels. There is significant, but saturable, first-pass elimination in the liver. Peak photosensitivity varies significantly between individuals but typically lasts 3–6 months; thus, patients often require maintenance therapy. About 1.5–2 h before UVA exposure. Methoxsalen has a serum half-life of about 1 h, but the skin remains sensitive to light for 8–12 h.

**Therapeutic Uses**

Oral methoxsalen is available as a single 10-mg strength either as soft gelatin capsules (solubilized) or hard gelatin capsules (micronized crystals). The dose is 10–70 mg, depending on weight (0.4–0.6 mg/kg), taken about 1.5–2 h before UVA exposure. Though administration with food can decrease absorption, it may minimize nausea. Topical application of psoralsens followed by UVA exposure (topical PUVA) is also used for treatment. A lotion containing 1% methoxsalen is available for topical application for vitiligo. The methoxsalen lotion or capsules can be diluted in bathwater and used topically for localized palmoplantar (soak PUVA) or more diffuse (bath PUVA) areas to minimize systemic absorption. An extracorporeal solution is available for CTCL (see Photopheresis). ECP can be combined with adjunctive therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

**Photodynamic Therapy**

Photodynamic therapy combines the use of photosensitizing drugs and visible light for the treatment of dermatological disorders. Two drugs are approved for topical PDT: aminolevulinic acid and methylaminolevulinate. However, methylaminolevulinate is currently not commercially available in the U.S. Both are prodrugs that are converted into protoporphyrin IX within living cells (Figure 70–2). In the presence of specific wavelengths of light (see Table 70–6) and O2, protoporphyrin produces reactive oxygen species that oxidize cell membranes, proteins, and other biomolecules. The greatest risk in those receiving more than 200–250 treatments is phototoxicity and vitiligo, and there has been conflicting evidence regarding this association.

**Photopheresis**

Extracorporeal photopheresis (ECP) is a process in which extracorporeal peripheral blood mononuclear cells are separated using a leukapheresis-based method then exposed to UVA radiation in the presence of methoxsalen (Perotti and Sniecinski, 2015). Methoxsalen is injected directly into the extracorporeal plasma before radiation and reinfusion. The treated lymphocytes are returned to the patient, undergoing apoptosis over 48–72 h. The ECP is used for CTCL and off-label for various other T-cell–mediated diseases, including graft-versus-host disease, transplantation rejection, and scleroderma. Patients receive ECP therapy on two consecutive days every 2–4 weeks, and intervals are increased as the patient improves (Jawed et al., 2014). ECP can be combined with adjunctive therapies, including PUVA, topical chemotherapy, systemic chemotherapy, radiation, biological agents, and retinoids.

**Figure 70–2** Heme biosynthesis pathway. A. Under physiological conditions, heme inhibits the enzyme 6-aminolevulinic acid (δ-ALA) synthase by negative feedback. However, when ALA is provided exogenously, this control point is bypassed, leading to excessive accumulation of protoporphyrin IX and heme. B. Heme.
and mitochondrial structures, leading to apoptosis. The epidermis, sebaceous glands, and neoplastic cells accumulate more porphyrin than other cutaneous cells and structures, providing some preferential targeting of therapy (Rkein and Ozog, 2014). PDT is approved for use on precancerous actinic keratosis. It is also used off label for superficial nonmelanoma skin cancers, acne, and photorejuvenation. Incoherent (nonlaser) and laser light sources have been used for PDT. The wavelengths chosen must include those within the action spectrum of protoporphyrin (see Table 70–6) and ideally those that permit maximum skin penetration. Light sources in use emit energy predominantly in the blue portion (maximum porphyrin absorption) or the red portion (better tissue penetration) of the visible spectrum. Because the \( t_{1/2} \) of the accumulated porphyrins is about 30 h, patients should protect their skin from sunlight and intense light for at least 48 h after treatment to prevent phototoxic reactions.

**Sunscreens**

Sunscreens provide temporary photoprotection from the acute and chronic effects of sun exposure. They are an important component of a comprehensive sun protection approach along with minimizing sun exposure and using photoprotective gear. The regular use of sunscreen is efficacious in reducing photocarcinogenesis and photoaging (Mancebo et al., 2014). The SPF is defined as the ratio of the minimal dose of incident sunlight that will produce erythema (sunburn) on skin with the sunscreen in place to the dose that evokes the same reaction on skin without the sunscreen. SPF is primarily a measure of UVB protection and does not provide information regarding UVA coverage. In 2011, the FDA published new guidelines for labeling and effectiveness testing of sunscreens (Mancebo et al., 2014). UVA protection is now assessed using the CW method, and products with a CW of 370 nm or greater may be labeled as “broad spectrum.” Sunscreens providing broad-spectrum coverage with an SPF 15 or greater may include a claim on their labeling that use “decreases risk of skin cancer and early aging caused by the sun.” Sunscreens should be applied liberally 15–30 min prior to sun exposure and reapplied every 2 h. If activities involve swimming or sweating, water-resistant sunscreens are recommended and should be reapplied every 40 or 80 min depending on their labeling.

The major active ingredients of available sunscreens include organic agents (“chemical blockers”) that absorb UV radiation in the UVB or UVA ranges, then convert it to heat energy and inorganic agents (“physical blockers”) that contain particulate materials that act by scattering or reflecting visible, UV, and infrared radiation to reduce its transmission to the skin. The current FDA-approved active sunscreen ingredients are listed next.

**Inorganic Agents**

The two inorganic agents available in the U.S. are zinc oxide and titanium dioxide. They provide UVA and UVB protection. Newer microsize and nanosize particle formulations are less opaque and more cosmetically appealing.

**Organic UVA Filters**

Currently available UVA filters in the U.S. include benzophenones (oxybenzone, dihydroxybenzene, sulisobenzone); dibenzoylethanes (avobenzone); anthralsates (meradimate); and camphors (ecamsule). Additional UVA filters are used in other countries but are not currently available in the U.S.

**Organic UVB Filters**

There are numerous UVB filters, including aminobenzoates (PARA and padimate O); cinnamates (cinoxate, octinoxate); salicylates (trolamine salicylate, homosalate, octisalate); octocrylene; and ensulizole.

**Antihistamines**

Histamine (see Chapter 39) is a potent vasodilator, bronchial smooth muscle constrictor, and stimulant of nociceptive itch receptors. Additional chemical itch mediators acting as pruritogens on C fibers include neuropeptides, prostaglandins, serotonin, acetylcholine, and bradykinin. Furthermore, receptor systems (e.g., vanilloid, opioid, and cannabinoid receptors) on cutaneous sensory nerve fibers may modulate itch and offer novel future targets for antipruritic therapy.

Histamine is in mast cells, basophils, and platelets. Human skin mast cells express \( H_1, H_2, \) and \( H_3 \) receptors but not \( H_4 \) receptors. Both \( H_1 \) and \( H_2 \) receptors are involved in wheal formation and erythema, whereas only the \( H_4 \) receptor agonists cause pruritus (see Chapter 39). However, blockade of \( H_4 \) receptors does not totally relieve itching, and combination therapy with \( H_1 \) and \( H_2 \) antagonists may be superior to the use of \( H_4 \) antagonists alone.

Oral antihistamines, particularly \( H_1 \) receptor antagonists, have anticholinergic activity and are sedating (see Chapter 39), making them useful for the control of pruritus. First-generation sedating \( H_1 \) receptor antagonists include hydroxyzine, diphenhydramine, promethazine, and cyproheptadine (Simons and Simons, 2008). Doxepin is a good alternative to traditional oral antihistamines for severe pruritus. A 5% topical cream formulation of doxepin, which can be used in conjunction with low- to moderate-potency topical glucocorticoids, is also available. The antipruritic effect from topical doxepin is comparable to that of low-dose oral doxepin therapy. Allergic contact dermatitis to doxepin has been reported. Topical diphenhydramine formulations available OTC also carry a significant risk of allergic contact dermatitis. Second-generation \( H_1 \) receptor antagonists lack anticholinergic side effects and are described as nonsedating largely because they do not cross the blood-brain barrier (Simons and Simons, 2008). They include cetirizine, levocetirizine, loratadine, desloratadine, and fexofenadine.

**Antimicrobial Agents**

**Antibiotics**

Antibiotic agents are frequently used to treat SSTIs. Several antimicrobial agents, such as tetracyclines, macrolides, and dapsone, also have anti-inflammatory properties, which make them useful for noninfectious conditions, such as acne vulgaris, rosacea, granulomatous diseases, neutrophilic dermatoses, and autoimmune bullous diseases (Bhatia, 2009).

Topical agents are very effective for the treatment of superficial bacterial infections and acne vulgaris (Drucker, 2012). Systemic antibiotics also are prescribed commonly for acne and deeper bacterial infections. The pharmacology of individual antibacterial agents is discussed in Section VI, Chemotherapy of Microbial Diseases. Only the topical and systemic antibacterial agents principally used in dermatology are discussed here.

**Acne**

Acne vulgaris is the most common dermatological disorder treated with either topical or systemic antibiotics (Eichenfield et al., 2013). The gram-positive anaerobe Propionibacterium acnes is a component of normal skin flora that proliferates in the obstructed, lipid-rich lumen of the pilosebaceous unit, where \( O_2 \) tension is low. Propionibacterium acnes generates free fatty acids from sebum and interacts with toll-like receptors, which promote microcomedo formation and inflammatory lesions (Das and Reynolds, 2014). Suppression of cutaneous P. acnes with antibiotic therapy is correlated with clinical improvement.

**Topical antimicrobials** commonly used in acne include benzoyl peroxide, clindamycin, erythromycin, and antibiotic–benzoyl peroxide combinations. Topical monotherapy with clindamycin or erythromycin is not recommended due to a slower onset of action and potential for development of bacterial resistance; therefore, addition of benzoyl peroxide or use of combination antibiotic–benzoyl peroxide products is recommended to improve efficacy and decrease emergence of antibiotic-resistant bacteria (Eichenfield et al., 2013). Other topical antimicrobials used in treating acne include azelaic acid, dapsone, metronidazole, sulfacetamide, and sulfaacetamide/sulfur combinations.

**Systemic therapy** is prescribed for patients with acne vulgaris that is more extensive or resistant to topical therapy. There are data to support the
use of tetracyclines (doxycycline, minocycline, tetracycline); macrolides (azithromycin, erythromycin); and trimethoprim-sulfamethoxazole. Other antibiotics that decrease the extent of the infection or the inflammatory response to *P. acnes* may be effective as well. Antibiotics usually are administered once or twice daily, and 6–8 weeks is required for visible clinical results, with maximum effect sometimes requiring 3–6 months (Eichenfield et al., 2013). Doses are tapered after control is achieved. Concomitant use with topical benzoyl peroxide may decrease development of antibiotic-resistant bacteria.

The tetracyclines are the most commonly employed antibiotics because they are inexpensive, effective, and safe. They should not be used during pregnancy or in patients younger than 8 years. Although agents in the tetracycline class are antimicrobials, efficacy in acne may be more dependent on anti-inflammatory activity. Minocycline and doxycycline have better GI absorption than tetracycline and may be given with food to minimize GI side effects. Minocycline may be less photosensitizing than either tetracycline or doxycycline. Minocycline’s adverse effects may include vestibular toxicity, hyperpigmentation of the skin and mucosa, serum sickness–like reactions, and drug-induced lupus erythematosus. With all the tetracyclines, vaginal candidiasis is a common complication that is readily treated with administration of antifungal drugs.

**Cutaneous Bacterial Infections**

Numerous organisms may cause cutaneous infections ranging from benign to life-threatening. Clinical presentation and treatment depend on the depth of cutaneous involvement, immune status of the patient, causative organism, and local antibiotic resistance patterns (Rajan, 2012; Stevens et al., 2014). Gram-positive organisms, including *Staphylococcus aureus* and *Streptococcus pyogenes*, are the most common cause of SSTIs. Patients who are diabetic or immunosuppressed are at risk for severe, recurrent, or atypical infections.

**Topical Therapy.** Topical therapy is frequently used for superficial bacterial infections, wounds, and burns. The use of topical antibiotics on clean surgical wounds without signs of infection is not recommended as it does not reduce the rate of infection compared to nonantibiotic ointment or no ointment, and there is a risk of contact dermatitis to topical antibiotics (Levender et al., 2012) and counterproductive selection of resistant bacterial strains.

**Mupirocin.** Mupirocin inhibits protein synthesis by binding to bacterial isoleucyl-tRNA synthetase. Mupirocin is effective for treatment of *S. aureus* and *S. pyogenes*, but it is inactive against normal skin flora or anaerobes. Mupirocin is available as a 2% ointment or cream, applied two or three times daily for 5–10 days. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014). A nasal formulation is indicated to eradicate MRSA nasal colonization. It is applied intranasally twice a day for 5 days and often combined with daily chlorhexidine or dilute sodium hypochlorite washes for the body. Prolonged suppression may be achieved with repeat monthly courses.

**Retapamulin.** Retapamulin selectively inhibits bacterial protein synthesis by interacting at a unique site on the 30S subunit of bacterial ribosomes. It is active against multiple gram-positive organisms, including *S. aureus* and *S. pyogenes*, and against anaerobes. Retapamulin ointment 1% is FDA approved for the topical treatment of impetigo caused by susceptible strains of *S. aureus* or *S. pyogenes* in patients 9 months or older. The recommended regimen for impetigo is twice daily for 5 days (Stevens et al., 2014).

**Bacitracin, Neomycin, and Polymyxin B.** These agents are sold alone or in various combinations with other ingredients (e.g., hydrocortisone, lidocaine, or pramoxine) in a number of OTC formulations. Bacitracin inhibits staphylococci, streptococci, and gram-positive bacilli. Neomycin is active against staphylococci and most gram-negative bacilli. Polymyxin B is active against aerobic gram-negative bacilli, including *Pseudomonas aeruginosa*. Both bacitracin and neomycin are relatively common causes of allergic contact dermatitis, especially in patients with stasis dermatitis or otherwise disrupted skin (Drucker, 2012).

**Gentamicin.** Gentamicin is an aminoglycoside that inhibits protein synthesis by binding to the 30S subunit of bacterial ribosomes. It has activity for certain gram-positive bacteria, including *S. aureus*, and gram-negative bacteria, including *P. aeruginosa*. Gentamicin sulfate 0.1% cream or ointment may be applied three or four times daily to affected areas.

**Silver Sulfadiazine.** Silver sulfadiazine binds to bacterial DNA and inhibits replication. It is bactericidal against gram-positive bacteria, including MRSA, and gram-negative bacteria, including *P. aeruginosa*. Silver sulfadiazine is most frequently used in the treatment of partial-thickness burns or lower extremity venous stasis ulcers. However, recent studies have failed to demonstrate efficacy in these settings (Miller et al., 2012). Rarely, argyria has developed in patients using silver sulfadiazine over extensive areas of the body (Browning and Levy, 2008).

**Mafenide.** Mafenide acetate is a topical sulfonamide, although its mechanism of action may be distinct from other sulfonamides. Mafenide is approved as adjunctive therapy for burn wounds and is available as either an 85-mg/g cream or a 5% topical solution supplied as 50-g packets of powder that must be reconstituted. It exerts broad bacteriostatic action against many gram-positive and gram-negative organisms, including *P. aeruginosa* and some anaerobes. The high solubility of mafenide allows it to diffuse easily through eschar and devascularized tissue, which is beneficial for treating subeschar burn wound infection. Mafenide and its metabolites inhibit carbonic anhydrase, so treated patients may be at risk for metabolic acidosis, especially if they have renal failure or if mafenide is applied to large surface areas. Other potential adverse effects include pain or burning sensation with application, facial edema, allergic contact dermatitis, and rarely hemolytic anemia in patients with G6PD deficiency.

**Systemic Therapy.** Deeper or complicated SSTIs typically require systemic administration of antimicrobials, which are also useful for superficial infections with diffuse involvement or that are not responding to topical therapy. Because SSTIs are most commonly caused by streptococcal and staphylococcal species, penicillins (especially β-lactamase–resistant β-lactams) and cephalosporins are the systemic antibiotics used most frequently in their treatment. A growing concern is the increased incidence of SSTIs with hospital- and community-acquired MRSA and drug-resistant pneumococci. Common outpatient treatment options for MRSA include clindamycin, doxycycline, and trimethoprim-sulfamethoxazole. When coverage for both MRSA and streptococci is needed, clindamycin alone or the combination of either doxycycline or trimethoprim-sulfamethoxazole with a β-lactam may be used (Stevens et al., 2014). Clindamycin should not be used as empiric therapy if local resistance rates are greater than 10%–15% (Stevens et al., 2014). Treatment options for more severe or complicated SSTIs that provide coverage for MRSA include vancomycin, linezolid, quinupristin-dalfopristin, and daptomycin. More recent additions to this armamentarium include dalbavancin, oritavancin, telavancin, teidizolid, and ceftaroline.

**Antifungal Agents**

Fungal infections are amongst the most common causes of skin disease in the U.S., and numerous effective topical and oral antifungal agents have been developed. The pharmacology, uses, and toxicities of antifungal drugs are discussed in Chapter 61. This section addresses the management of common superficial cutaneous mycoses. Recommendations for cutaneous antifungal therapy are summarized in Table 70–7. Topical antifungal agents used for superficial mucocutaneous mycoses are listed in Table 70–8.

**Dermatophyte Infections of the Skin (Tinea Corporis, Cruris, and Pedis)**

The dermatophyte infections (tinea corporis, cruris, and pedis) generally respond to topical antifungals, including allylamines (naftifine, terbinafine); benzylamines (butenafine); azoles ( econazole, luliconazole); and ciclopirox (Rotta et al., 2013). Allylamines and benzylamines may provide a more sustained clinical cure compared to azole antifungals (Rotta et al., 2013). Bacterial superinfection of tinea pedis can occur, and antifungal agents such as econazole and ciclopirox that also provide some bacterial coverage may be useful in these situations. Systemic therapy with terbinafine, fluconazole, itraconazole, or griseofulvin is used

when there is more extensive cutaneous involvement or a poor response to topical therapy.

**Dermatophyte Infections of the Hair and Follicles**

Dermatophyte infections of the hair (tinea capitis) or follicularly based infections of the skin (Majocchi granuloma) require systemic therapy. Griseofulvin has been the traditional medication for tinea capitis, and treatment failure is often related to inadequate dosage or length of treatment. Terbinafine may be more effective for *Trichophyton tonsurans*, which is the most common cause of tinea capitis in the U.S. (Elewski et al., 2008). Fluconazole and itraconazole are also effective (Gupta and Paquet, 2013).

**Onychomycosis**

Onychomycosis is a fungal infection of the nails that is commonly caused by dermatophytes or candida. Onychomycosis is most effectively treated with systemic therapy (de Sa et al., 2014). Fungal infection should be confirmed prior to initiating oral therapy. There are other causes of nail dystrophy, and approximately one-third of nails with clinically suspected onychomycosis do not have fungal infection (Mehregan and Gee, 1999). Terbinafine is the most effective treatment of dermatophyte onychomycosis, with typical adult dosing of 250 mg daily for 6 weeks for fingernails and 12 weeks for toenails. Terbinafine remains in the nails for several weeks after medication administration has ceased, and some studies have utilized pulsed dosing of terbinafine 500 mg daily for 1 week per month for 3 months based on this finding. Itraconazole is another effective option for dermatophyte onychomycosis and is more effective than terbinafine for candidal onychomycosis. Itraconazole persists in the nail for 6–9 months after administration has ceased. Traditional adult dosing for itraconazole is 200 mg daily for 12 weeks; however, pulsed dosing is an alternative option because itraconazole of its long persistence after administration has ceased. Itraconazole pulsed dosing is 400 mg daily for 1 week per month for 2 months for fingernails and 3 months for toenails, which may be more effective than traditional dosing with fewer side effects. Fluconazole is an alternative option that may be useful in patients who cannot use terbinafine or itraconazole. Griseofulvin, used in the past, is less efficacious and requires much longer treatment courses; it is no longer a preferred option. Topical antifungals approved for onychomycosis include ciclopirox lacquer, efinaconazole, and tavaborole. These topical antifungals require a 48-week treatment course. They may be useful for patients with mild-to-moderate onychomycosis not involving the nail matrix or in patients who are not candidates for systemic therapy (Gupta et al., 2014).

**Cutaneous Candidiasis**

Cutaneous candidiasis is typically treated with topical azole antifungals or nystatin when localized. Systemic azole antifungals such as fluconazole or itraconazole may be needed for more recalcitrant or severe cases.

**Malassezia Infections**

*Pityriasis versicolor and seborrheic dermatitis* are caused by *Malassezia* ( pityrosporum) species and are frequently treated with azole antifungals in cream or shampoo formulations. Topical ciclopirox and terbinafine are also approved for use. Additional topical therapies include selenium sulfide, pyrithione zinc, sodium sulfacetamide, and sulfur with or without salicylic acid. Oral fluconazole or itraconazole are sometimes used for pityriasis versicolor when diffuse or resistant. Oral terbinafine does not reach adequate concentrations in the superficial stratum corneum to be effective.

**Antiviral Agents**

Viral infections of the skin by HPV, HSV, molluscum contagiosum virus, and VZV are common and produce a variety of lesions, including warts or blisters. Acyclovir, famciclovir, and valacyclovir are often used systemically to treat HSV and VZV infections (see Chapter 62). Cidofovir and foscarnet are useful for treating acyclovir-resistant HSV. Topically, acyclovir, docosanol, penciclovir, and combination acyclovir/hydrocortisone are available for treating mucocutaneous HSV; however, they are less effective than systemic therapies (Sarnoff, 2014). Acyclovir is also available as a 50-mg buccal tablet for herpes labialis to be applied as a single dose to the upper gum just above the incisor tooth within 1 h of prodromal symptoms. Cidofovir is used off label topically or intraleisonally as treatment of anogenital warts caused by HPV. Topical cidofovir 1% gel or cream must be obtained through a compounding pharmacy. It is applied once daily for 5 consecutive days every other week for a maximum of six cycles. Additional treatments for genital warts are nonspecific cytodestructive or immunomodulatory therapies, which are discussed in further detail in other sections. Cytodestructive modalities include topical use of cryotherapy, podophyllin (podophyllum resin) or podofilox (podophyllotoxin), and trichloroacetic acid. Topical immunomodulatory therapies include imiquimod and sancetchines. Also, intralesional or systemic interferons α, β may be useful for treating refractory or recurrent genital warts, but their use is limited by pain with multiple injections for intraleisional use and by potential for severe side effects with systemic use (Smith et al., 2007).

**Agents Used to Treat Infestations**

Infestations with ectoparasites such as lice and scabies are common throughout the world. These conditions have a significant impact on public health in the form of disabling pruritus, secondary infection, and, in the case of the body louse, transmission of life-threatening illnesses such as typhus. Topical and oral medications are available to treat these infestations (Diamantis et al., 2009).

- **Permethrin** is a synthetic pyrethroid that interferes with insect Na+ transport proteins, causing neurotoxicity and paralysis. Resistance due to mutations in the transport protein has been reported and appears to be increasing. A 5% cream is available by prescription for the treatment of scabies, and a 1% lotion or cream rinse is available OTC for the treatment of lice. Permethrin is approved for use in infants 2 months or older. Other OTC agents used in the treatment of lice are pyrethrins plus piperonyl butoxide in various formulations and acetic acid plus isopropanol shampoo.
- **Lindane** is an organochloride compound that induces neuronal hyperstimulation and eventual paralysis of parasites. Due to several cases of neurotoxicity in humans, the FDA has labeled lindane as a second-line drug in treating pediculosis and scabies and has highlighted the

(Continued)
potential for neurotoxicity in children and adults weighing less than 50 kg and patients with underlying skin disorders such as atopic dermatitis and psoriasis. Lindane is contraindicated in premature infants and patients with seizure disorders.

- **Malathion** is an organophosphate that inhibits acetylcholinesterase in lice, causing paralysis and death. It is approved for treatment of head lice in children 6 years and older. The current formulation of malathion lotion contains 78% isopropyl alcohol and is flammable. Detailed information on malathion’s actions and adverse effects may be found in Chapter 10.

- **Benzyl alcohol** 5% lotion is approved for the treatment of lice in patients 6 months and older. Benzyl alcohol inhibits lice from closing their respiratory spiracles, which allows the vehicle to obstruct the spiracles and causes the lice to asphyxiate. There may be less potential for development of resistance with this mechanism of action compared to traditional pesticides.

- **Ivermectin** is an anthelmintic drug (see Chapter 55) approved for oral treatment of onchocerciasis and strongyloidiasis. Recently, topical ivermectin 0.5% lotion was approved to treat lice in patients 6 months and older and 1% cream to treat rosacea. Ivermectin is also effective in the off-label treatment of scabies. Because ivermectin does not cross the human blood-brain barrier, there is no major CNS toxicity; minor CNS side effects with oral administration may include dizziness, somnolence, vertigo, and tremor. Topical administration may cause local irritant effects, such as conjunctivitis, eye irritation, dry skin, or skin-burning sensation, although these occurred in fewer than 1% of patients during clinical trials. For both scabies and lice, ivermectin typically is given at an oral dose of 200 μg/kg, which may be repeated in 1 week. In cases of crusted scabies, longer treatment cycles of oral ivermectin may be needed, sometimes in addition to topical keratolytics and scabicides (Ortega-Loayza et al., 2013). It should not be used in children weighing less than 15 kg.

- **Spinosad** 0.9% topical suspension is approved for treatment of head lice in patients 6 months or older. Spinosad causes CNS excitation and involuntary muscle contractions, leading to insect paralysis and death.

Less effective topical treatments for scabies and lice include 10% crotonitom cream and lotion and extemporaneously compounded 5%–10% precipitated sulfur in petrolatum. Precipitated sulfur may be useful for patients in whom other therapies are contraindicated or not approved; it is typically applied once daily for 3–5 consecutive days.

### Antimalarial Agents

The antimalarial agents chloroquine, hydroxychloroquine, and quinacrine are used in dermatology to treat dermatoses such as cutaneous lupus erythematosus, cutaneous dermatomyositis, polymorphous light eruption, porphyria cutanea tarda, and sarcoidosis (only hydroxychloroquine is FDA approved for treating lupus erythematosus). The mechanism by which antimalarial agents exert their anti-inflammatory therapeutic effects is uncertain but may involve inhibition of endosomal Toll-like receptor signaling, resulting in reduced B-cell and dendritic cell activation (Kalia and Dutz, 2007). The usual dosages of antimalariais are hydroxychloroquine 200 mg twice a day (maximum of 6.5 mg/kg/d); chloroquine 250–500 mg/d (maximum of 3 mg/kg/d); and quinacrine 100–200 mg/d. Patients with porphyria cutanea tarda require lower doses of antimalariais to avoid severe hepatotoxicity. There is strong evidence that smoking decreases the effectiveness of antimalariais in the treatment of cutaneous lupus erythematosus, so smoking cessation is important (Chasset et al., 2015). Clinical improvement may be delayed for several months. If there is no improvement after 3 months of hydroxychloroquine, then quinacrine may be added (in the U.S., quinacrine must be obtained through compounding pharmacies). Dose-dependent ocular toxicity occurs with chloroquine more often than hydroxychloroquine and is rare to nonexistent with quinacrine. The potential toxic effects of antimalarial agents are described further in Chapter 53.

### Cytotoxic and Immunosuppressant Drugs

Cytotoxic and immunosuppressant drugs are used in dermatology for immunologically mediated diseases such as psoriasis, autoimmune blistering diseases, and leukocytoclastic vasculitis. See Table 70–9 for their mechanisms of action.

### Antimetabolites

**Methotrexate** is used for moderate-to-severe psoriasis. It suppresses immunocompetent cells in the skin, and it also decreases the expression of CLA-positive T cells and endothelial cell E-selectin, which may account for its efficacy. Methotrexate is useful in treating a number of other dermatological conditions, including atopic dermatitis, pityriasis lichenoides et varioliformis, lymphomatoid papulosis, sarcoidosis, pemphigus vulgaris, pityriasis rubra pilaris, lupus erythematosus, dermatomyositis, and CTCL.

Methotrexate often is used in combination with phototherapy and photochemotherapy or other systemic agents. Widely used oral regimens include 10–25 mg once weekly as a single dose or as three divided doses given at 12-h intervals, with similar effectiveness using either regimen, or intramuscular administration of 10–25 mg injected once weekly (maximum of 30 mg/week) (Menter et al., 2009b).

Doses must be decreased for patients with impaired renal clearance. **Methotrexate should not be administered with probenecid, trimethoprim-sulfamethoxazole, salicylates, or other drugs that can compete with it for protein binding and thereby raise plasma concentrations to levels that...**

**NOTES**

- 08/09/17  5:23 PM
Cyclophosphamide has many adverse effects (see Chapter 66), including the risk of secondary malignancy and myelosuppression, and is used only in the most severe, recalcitrant dermatological diseases.

**Mechlorethamine hydrochloride and carmustine** are used topically to treat CTCL (Jawed et al., 2014). It is important to monitor CBCs and liver function tests because systemic absorption can cause bone marrow suppression and hepatitis. Other side effects include allergic contact dermatitis, irritant dermatitis, secondary cutaneous malignancies, and pigmentary changes. Carmustine also can cause erythema and posttreatment telangiectasias.

**Microtubule Inhibitors**

**Vinblastine** is approved for systemic use in Kaposi sarcoma and advanced CTCL. Intranasal vinblastine also is used to treat Kaposi sarcoma (Regnier-Rosencher et al., 2013).

**Podophyllin (podophyll resin)** is a mixture of chemicals from the plant Podophyllum peltatum (mandrake or May apple) that contains podophyllotoxin (podophlox), which binds to microtubules and causes mitotic arrest in metaphase (Fathi and Tsoukas, 2014). In the U.S., it must be obtained through a compounding pharmacy. Podophyllin resin 25% is applied topically by a physician and left in place for no longer than 2–6 h weekly for the treatment of anogenital warts. Irritation and ulcerative local reactions are the major side effects. It should not be used in the mouth or during pregnancy. It is recommended that the use of provider-administered podophyllin resin be replaced by the purified podophyllotoxin (podo- filox) for patient-administered use. Podofilox is available as a 0.5% gel or solution for at-home application two times daily for 3 consecutive days, repeated weekly as needed for up to four cycles.

**Other Cytotoxic Agents**

**Bleomycin** is used off label intralesionally for palliative treatment of squamous cell carcinoma and recalcitrant warts and has cytotoxic and pro-inflammatory effects. Intranasal injection of bleomycin into the digits has been associated with a vasospastic response that mimics Raynaud phenomenon. Other potential adverse reactions include local skin necrosis and flagellate hyperpigmentation. Systemic bleomycin has been used off label for Kaposi sarcoma (see Chapter 66) (Regnier-Rosencher et al., 2013).

**Liposomal anthracyclines** (specifically doxorubicin) may provide first-line monotherapy for advanced Kaposi sarcoma (Regnier-Rosencher et al., 2013).

**Ingenol mebutate** gel, an extract from the plant Euphorbia peplus, is FDA approved for actinic keratosis (Micali et al., 2014). In experimental studies, it was reported to rapidly cause mitochondrial swelling and apoptosis of dysplastic keratinocytes. The gel is applied once daily for 2–3 consecutive days. Adverse effects may include local skin irritation, pain, pruritus, and infection at application site; periorbital edema; nasopharyngitis; and headache. Cases of allergic contact dermatitis and reactivation of herpes zoster have been reported.

**Azathioprine and Mycophenolate Mofetil**

**Azathioprine** is discussed in Chapter 35. In dermatological practice, the drug is used off label as a steroid-sparing agent for autoimmune and inflammatory dermatoses, including pemphigus vulgaris, bullous pemphigoid, dermatomyositis, atop dermatis, chronic actinic dermatitis, lupus erythematosus, psoriasis, pyoderma gangrenosum, and Behçet disease.

Azathioprine is cleaved to 6MP, which in turn is converted to additional metabolites that inhibit de novo purine synthesis (see Figure 51–5 and Chapter 66). The level of thiopurine S-methyltransferase (TPMT) enzyme activity should be measured before initiating azathioprine therapy because low levels of TPMT activity are associated with increased drug toxicity (see Chapter 66). In general, the starting dosage is 1–2 mg/kg/d. Careful laboratory monitoring is important, especially in those with diminished TPMT activity.

**Mycophenolate mofetil** and mycophenolate sodium are immunosuppressants approved for prophylaxis of organ rejection in patients with
renal, cardiac, and hepatic transplants (see Chapter 35). Mycophenolate mofetil is a prodrug that is hydrolyzed to mycophenolic acid by plasma esterases; the salt of the acid, mycophenolate sodium, is available in an enteric-coated formulation. Mycophenolic acid functions as a specific inhibitor of T- and B-lymphocyte activation and proliferation through inhibition of inosine monophosphate dehydrogenase, thereby reducing GMP synthesis by the de novo purine synthetic pathway. Lymphocytes are vulnerable due to their lack of the salvage pathway for purine synthesis. The drug also may enhance apoptosis.

Mycophenolate mofetil is used off label increasingly to treat inflammatory and autoimmune diseases in dermatology; dosages typically range from 2 to 3 g/d orally in adults or 30–50 mg/kg/d in pediatric patients, given in divided doses twice daily. This agent is particularly useful as a corticosteroid-sparing agent in the treatment of autoimmune blistering disorders and has been used effectively in the treatment of inflammatory diseases such as psoriasis, atopic dermatitis, and pyoderma gangrenosum. Isolated cases of PML and pure red cell aplasia have been reported in solid organ transplant patients receiving mycophenolate mofetil. The most common side effects of mycophenolate mofetil are dose-dependent GI symptoms (e.g., diarrhea, nausea, and abdominal pain). Enteric-coated mycophenolate sodium improves GI tolerability; the enteric coating delays absorption until the medication reaches the small intestine rather than occurring in the stomach.

Calcineurin Inhibitors

The mechanisms of action and clinical pharmacology of calcineurin inhibitors are described in Chapter 35, and Figure 35–2 shows their main molecular effects as immunosuppressants.

Cyclosporine is a potent immunosuppressant isolated from the fungus Tolypocladium inflatum. Cyclosporine is FDA approved for the treatment of psoriasis. A modified microemulsion formulation has increased bioavailability and more consistent absorption than the original formulation. Other cutaneous disorders that typically respond well to cyclosporine are atopic dermatitis, alopecia areata, epidermolysis bullosa acquisita, pemphigus vulgaris, bullous pemphigoid, lichen planus, and pyoderma gangrenosum. The usual oral dosage of the modified formulation is 2.5 to 5 mg/kg/d, often given in two divided doses (Menter et al., 2009b; Sidbury et al., 2014).

Hypertension and renal dysfunction are the major adverse effects associated with the use of cyclosporine. These risks can be minimized by monitoring serum creatinine (which should not rise more than 30% above baseline), calculating creatinine clearance or glomerular filtration rate in patients on long-term therapy or with a rising creatinine, maintaining a daily dose of less than 5 mg/kg, and regularly monitoring blood pressure. Alternation with other therapeutic modalities may diminish cyclosporine toxicity. Patients with psoriasis who are treated with cyclosporine are at increased risk of cutaneous, solid organ, and lymphoproliferative malignancies. The risk of cutaneous malignancies is compounded in patients who have received phototherapy with PUVA.

Tacrolimus is available in a topical form for the treatment of skin disease and also is marketed in oral and injectable formulations. Systemic tacrolimus has shown some efficacy in the off-label treatment of inflammatory skin diseases such as psoriasis, pyoderma gangrenosum, and Behçet disease. When tacrolimus is administered systemically, the most common side effects are hypertension, nephrotoxicity, neurotoxicity, GI symptoms, hyperglycemia, and hyperlipidemia.

Topical formulations (0.03% and 0.1%) of tacrolimus ointment are approved for the treatment of atopic dermatitis in adults and in children 2 years or older for 0.03% ointment and 16 years or older 0.1% ointment. Other uses include for treatment of intertriginous psoriasis, vitiligo, mucosal lichen planus, graft-versus-host disease, allergic contact dermatitis, and rosacea. Ointment is applied to the affected area two times daily and generally is well tolerated. Common side effects at the site of application are transient erythema, burning, and pruritus. Other adverse effects include skin tingling, flu-like symptoms, headache, alcohol intolerance, folliculitis, acne, and hyperesthesia. Systemic absorption generally is very low and decreases with resolution of the dermatitis. Topical tacrolimus should be used with extreme caution in patients with Netherton syndrome; these patients may develop elevated blood levels of the drug after topical application (Eichenfield et al., 2014).

Pimecrolimus (as a 1% cream) is approved for the treatment of atopic dermatitis in patients 2 years and older. Its mechanism of action and side-effect profile are similar to those of tacrolimus. It has low-to-negligible systemic absorption after topical application.

Tacrolimus and pimecrolimus are approved as second-line agents for short-term and intermittent treatment of atopic dermatitis in patients unresponsive to, or intolerant of, other treatments. Unlike topical corticosteroids, they do not carry the risk of skin atrophy and may be especially useful as steroid-sparing agents or for use on sensitive skin sites (e.g., eyelids, face, skin folds) or areas with steroid-induced atrophy.

mTOR Inhibitors

Sirolimus causes immunosuppressive and antiproliferative effects through inhibition of mTOR as part of the PI3 kinase/Akt/mTOR pathway (see Figures 3–16, 35–2, and 67–4). The mTOR inhibitors are established treatments for posttransplant immunosuppression (Chapter 35) and as antineoplastic agents for malignancies such as renal and hepatocellular carcinoma (Chapter 67). Off-label use of mTOR inhibitors in dermatology includes the treatment of tuberous sclerosis complex, pachyonychia congenita, complex vascular anomalies, and inflammatory dermatoses such as systemic sclerosis (Fogel et al., 2015). Systemic mTOR inhibitors may be associated with several side effects, with dermatologic side effects amongst the most common, including stomatitis, mucositis, inflammatory cutaneous eruptions, and nail changes such as paronychia (Fogel et al., 2015). Topical formulations have been used to decrease the risk of side effects associated with systemic therapy. Newer semisynthetic analogues of sirolimus such as everolimus and temsirolimus are available and have improved water solubility and efficacy.

Immunomodulators and Anti-inflammatory Agents

Imiquimod exerts immunomodulatory effects by acting as a ligand at toll-like receptors in the immune system and inducing the cytokines IFN-α, TNF-α, and IL-1, IL-6, IL-8, IL-10, and IL-12.

Imiquimod cream is available in 2.5%, 3.75%, and 5% strengths. Approved for the treatment of genital warts, imiquimod 5% cream is applied to genital or perianal lesions three times a week until resolution of warts or up to a 16-week period (and repeated as necessary) (Pathi and Tsoukas, 2014). Imiquimod also is approved for the treatment of actinic keratoses, with various regimens used (Micali et al., 2014). No more than 36 single-use packets per 16-week course of therapy should be prescribed for actinic keratoses. The 5% cream is also FDA approved for the treatment of superficial BCCs at a dosage of five applications/week for 6 weeks. Off-label applications include the treatment of nongenital warts, molluscum contagiosum, extramammary Paget disease, and Bowen disease. Irritant reactions occur in virtually all patients; the degree of inflammation parallels therapeutic efficacy.

Sinecatchins are partially purified green tea extracts containing a mixture of 85%–95% catechins and other green tea components. They are approved for the topical treatment of external genital and perianal warts in immunocompetent patients more than 18 years of age. The mechanism of action is unclear but may include a combination of antioxidant, anti viral, antiangiogenic, proapoptotic, and immunomodulatory activities. The sinecachin 15% ointment is applied three times daily for up to 16 weeks until clearance of the warts. The most common side effects are local skin reactions, including erythema, pruritus or burning, pain, superficial ulceration, and edema, with the intensity of local reactions peaking between 2 and 4 weeks of use. Local site reactions may be indicative of a positive clinical response, and patients are encouraged to treat them as tolerated.

Dapsone is used in dermatology for its anti-inflammatory properties, particularly in sterile (noninfectious) pustular diseases of the skin (Zhu
Dapsone prevents the respiratory burst from myeloperoxidase, suppresses neutrophil migration by blocking integrin-mediated adherence, inhibits adherence of antibodies to neutrophils, and decreases the release of eicosanoids and blocks their inflammatory effects. Dapsone is discussed further in Chapter 60.

Dapsone is approved for oral use in dermatitis herpetiformis and leprosy and for topical use in acne vulgaris. It is also particularly useful in the off-label treatment of linear IgA dermatosis, bullous systemic lupus erythematosus, erythema elevatum diutinum, and subcorneal pustular dermatosis. In addition, reports indicate efficacy in patients with acne fulminans, pustular psoriasis, lichen planus, Hailey-Hailey disease, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, leukocytoclastic vasculitis, Sweet syndrome, granuloma faciale, relapsing polychondritis, Behçet disease, urticarial vasculitis, pyoderma gangrenosum, and granuloma annulare.

The initial oral dosage is 50 mg/d, followed by increases of 25 mg/d at weekly intervals, titrated to the minimal dosage necessary for effect. Potential side effects of dapsone include methemoglobinemia and hemolytic anemia (G6PD level should be checked in all patients). The human cimetidine inhibits numerous CYPs and thereby reduces the N-hydroxylation of dapsone to the hydroxylamine metabolite that causes the methemoglobinemia. Other toxicities of dapsone include agranulocytosis, peripheral neuropathy, and psychosis.

**Thalidomide** is an anti-inflammatory, immunomodulatory, and antiangiogenic agent experiencing resurgence in the treatment of dermatological diseases (Wu et al., 2005). For details of its actions, see Chapter 36 under Immunostimulants and Figure 66–2 and associated text.

Thalidomide is FDA approved for the treatment of erythema nodosum leprosum. Reports also suggest its efficacy in actinic prurigo, aphthous stomatitis, Behçet disease, Kaposi sarcoma, the cutaneous manifestations of lupus erythematosus, and prurigo nodularis and urticarial prurigo. Thalidomide has been associated with increased mortality when used to treat toxic epidermal necrolysis. In utero exposure can cause limb abnormalities (phocomelia), as well as other congenital anomalies. **Thalidomide should never be taken by women who are pregnant or who could become pregnant while taking the drug. It also may cause an irreversible neuropathy. Because of its teratogenic effects, thalidomide use is restricted and requires both pharmacists and physicians to register in a risk evaluation and mitigation strategy (REMS) program. Newer analogues of thalidomide are available, including lenalidomide and pomalidomide.

### Targeted Immunotherapies for Psoriasis and Atopic Dermatitis

Targeted immunotherapies, including biological agents, are rapidly evolving for the treatment of psoriasis, as the underlying pathogenesis is better understood (Table 70–10). In addition, biological therapy for atopic dermatitis is on the horizon. The appeal of these targeted therapies is that they specifically target the activities of T lymphocytes and cytokines that mediate inflammation, whereas traditional systemic therapies are broadly immunosuppressive or cytotoxic. The pathogenesis of psoriasis and atopic dermatitis is discussed briefly next, followed by the relevant targeted therapies. Targeted therapies are discussed in further detail in Chapter 35.

Psoriasis is a chronic immune-mediated inflammatory disorder involving the innate and adaptive immune systems, with resultant abnormal keratinocyte proliferation (Figure 70–3). Psoriasis is not limited to the skin, as there can be psoriatic arthritis and other systemic manifestations. Previously thought to be primarily Th1 mediated, more recent developments demonstrate that the Th17/IL-17 pathway plays the most significant role (Girolomoni et al., 2012). Mediators of inflammation, such as IL-23, TNF-α, and IL-17 are key targets for therapy (Girolomoni et al., 2012; Sobell and Leonardi, 2014). In addition, therapies such as inhibitors of Jak and cyclic nucleotide PDEs) are useful to decrease expression or signal transduction of inflammatory cytokines (Sobell and Leonardi, 2014).

*No embryo-fetal toxicity in mice and non-human primates; no adequate, well controlled studies in pregnant women; use only if benefit justifies potential risk to fetus.*
Psoriasis is a prototypical inflammatory skin disorder in which specific T-cell populations are stimulated by cytokines such as TNF-α, IFN-γ, IL-23, and IL-17, which ultimately induce keratinocyte hyperproliferation and sustain chronic inflammation.

**Tumor Necrosis Factor Inhibitors**

Blockade of TNF-α reduces inflammation, decreases keratinocyte proliferation, and decreases vascular adhesion, resulting in improvement in psoriatic lesions. Because TNF-α inhibitors alter immune responses, patients on all anti-TNF-α agents are at increased risk for serious infection and for malignancies. Other adverse events include exacerbation of congestive heart failure and demyelinating disease in predisposed patients. All patients should be screened for tuberculosis, history of demyelinating disorder, cardiac failure, active infection, or malignancy prior to therapy. TNF-α inhibitors include monoclonal antibodies directed against TNF-α (adalimumab, infliximab) or a soluble TNF receptor that can bind TNF-α (etanercept) (see Chapter 35). All TNF-α inhibitors are able to bind both soluble and membrane-bound TNF, but the monoclonal antibodies against TNF-α with an IgG Fc portion are also able to activate complement-dependent cytotoxicity on binding of membrane-bound TNF-α. This may explain the increased efficacy of these agents in comparison to etanercept for treating granulomatous conditions as well as the higher risk of infection with their use.

**Etranercept** is a soluble, recombinant, fully human TNF receptor fusion protein consisting of two molecules of the ligand-binding portion of the TNF receptor (p75) fused to the Fc portion of IgG1. It binds both TNF-α and TNF-β. Etranercept is approved for plaque psoriasis and psoriatic arthritis in adults. Studies have shown etanercept to be safe and efficacious for pediatric psoriasis at dosing of 0.8 mg/kg (maximum 50 mg) once weekly (Bellodi Schmidt and Shah, 2015).

**Infliximab**, a mouse-human chimeric IgG1, monoclonal antibody directed against human TNF-α, is approved for treatment of chronic severe plaque psoriasis and psoriatic arthritis. The administration of infliximab via intravenous infusion can be a limiting factor; however, compared to other TNF-α inhibitors, its onset of action may be faster and efficacy greater. Neutralizing antibodies to infliximab may develop and lead to decreased efficacy over time. Concomitant administration of methotrexate or glucocorticoids may suppress this neutralizing antibody formation.

**Adalimumab** is a human IgG1 monoclonal antibody directed against TNF-α; thus, the risk for development of neutralizing antibodies is reduced compared to infliximab. Adalimumab is approved for treatment of plaque psoriasis and psoriatic arthritis in adults. Safety of adalimumab in pediatric patients for psoriasis is supported by its use in other conditions, such as juvenile idiopathic arthritis (Bellodi Schmidt and Shah, 2015). Adalimumab is also approved for treatment of hidradenitis suppurativa.

**Golimumab** and **certolizumab pegol** are TNF-α inhibitors that are currently approved for psoriatic arthritis but not psoriasis. However, studies of these medications for psoriatic arthritis also demonstrated improvement of plaque psoriasis, and a phase III trial of certolizumab pegol for plaque psoriasis demonstrated efficacy. Golimumab is a fully human monoclonal antibody against TNF-α with a longer t1/2 than other TNF-α inhibitors. Certolizumab pegol is a pegylated Fab fragment of a human monoclonal antibody against TNF-α. Because certolizumab pegol lacks the Fc portion, it is not able to activate complement-mediated cytotoxicity.

**IL-12/23 Inhibitors**

**Ustekinumab** is a human IgG1 monoclonal antibody directed against the common p40 subunit of IL-12 and IL-23. IL-12 promotes Th1 activity and related TNF-α and IFN-γ production, while IL-23 activates Th17 cells that produce IL-17A, which regulates tissue inflammation and autoimmune responses. Ustekinumab is approved for treatment of moderate-to-severe plaque psoriasis and psoriatic arthritis. After initial doses at weeks 0 and 4, it is administered every 12 weeks for the maintenance phase of therapy, which may be ideal for some patients. Studies have shown ustekinumab to be safe and efficacious in adolescent patients at the same dosing as adults (Bellodi Schmidt and Shah, 2015).

**IL-17 Inhibitors**

Keratinocytes are the major target for IL-17 in psoriasis, with IL-17 stimulation causing increased keratinocyte expression of inflammatory cytokines and other effects that contribute to epidermal hyperproliferation and barrier dysfunction. Clinical trials have demonstrated that IL-17 inhibitors are very efficacious for plaque psoriasis.

**Secukinumab** is a fully human IgG1 monoclonal antibody against IL-17A approved for the treatment of moderate-to-severe plaque psoriasis in adults. Additional IL-17 inhibitors in phase III clinical trials include **ixekizumab**, a humanized IgG1 monoclonal antibody against IL-17A, and **brodalumab**, a human monoclonal antibody against the IL-17 receptor...
Diphtheria toxin is a fusion protein composed of diphtheria toxin A and B fragments, which are responsible for the toxin's lethal effect on cells. The active fragment of diphtheria toxin is internalized by endocytosis. The active fragment of diphtheria toxin is internalized by endocytosis. The active fragment of diphtheria toxin is internalized by endocytosis. The active fragment of diphtheria toxin is internalized by endocytosis. The active fragment of diphtheria toxin is internalized by endocytosis.

**PDE4 Inhibitors**

Apremilast is an oral PDE4 inhibitor that increases intracellular cyclic AMP levels, thereby decreasing expression of inflammatory cytokines such as TNF-α and IL-23 and increasing expression of anti-inflammatory cytokines such as IL-10. Apremilast is approved for treatment of moderate-to-severe plaque psoriasis and psoriatic arthritis in adults. It has also shown efficacy for atopic dermatitis in a pilot study. The most common side effects are weight loss and depression.

**Jak Inhibitors**

Janus kinases are tyrosine kinases involved in cytokine receptor signaling, and Jak inhibition leads to decreased downstream activity of STAT, which modulates transcription of genes involved in cell growth, proliferation, and differentiation.

Tofacitinib is an oral Jak inhibitor approved for use in rheumatoid arthritis in adults. It has demonstrated efficacy for psoriasis in clinical trials and for atopic dermatitis in a pilot study.

**IL-4 Inhibitors**

Dupilumab is a fully human monoclonal antibody against the alpha subunit of IL-4R that inhibits both IL-4 and IL-13 signaling as they each exert their action through binding an IL-4Ra/IL-13Rα1 receptor complex (Beck et al., 2014). IL-4 and IL-13 are important mediators of the Th2 immune response that is involved in acute atopic dermatitis. Dupilumab has shown promising results in clinical trials, demonstrating significant improvement in disease severity and fewer skin infections compared to placebo (Beck et al., 2014). The most frequent adverse effects are nasopharyngitis and headache.

**Intravenous Immunoglobulin**

Intravenous immunoglobulin is prepared from fractionated pooled human sera derived from thousands of donors with various antigenic exposures (see Chapter 36). Preparations of IVIG are composed of more than 90% IgG, with minimal amounts of IgA, soluble CD4, CD8, HLA molecules, and cytokines. In dermatology, IVIG is used off label as an augmentation therapy for autoimmune bullous diseases, toxic epidermal necrolysis, connective tissue diseases, vasculitis, urticaria, atopic dermatitis, and graft-versus-host disease (Smith et al., 2007).

Although the mechanism of action of IVIG is not understood fully, proposed mechanisms include suppression of IgG production, accelerated catabolism of IgG, neutralization of complement-mediated reactions, neutralization of pathogenic antibodies, downregulation of inflammatory cytokines, inhibition of autoreactive T lymphocytes, inhibition of immune cell trafficking, and blockade of Fas-ligand/Fas-receptor interactions (Smith et al., 2007). IVIG is contraindicated in patients with severe selective IgA deficiency (IgA < 0.05 g/L). These patients may possess anti-IgA antibodies that place them at risk for severe anaphylactic reactions. Other relative contraindications include congestive heart failure and renal failure.

**Targeted Antineoplastic Agents**

Recent advances in understanding the molecular pathways and genetic alterations underlying cancer development have allowed for the rapid emergence of oncotherapeutic agents targeted against the specific molecules involved in tumor pathogenesis (Iwasaki et al., 2012; Jawed et al., 2014; John and Cowey, 2015). They are often better tolerated than conventional chemotherapeutic medications; however, adverse effects do still occur, with cutaneous toxicities amongst the most common. These therapies are discussed in further detail in Chapter 67.

**Targeted Therapies for Basal Cell Carcinoma**

Basal cell carcinoma is the most common malignancy in humans, and exposure to UV radiation plays a large role in its development, with intermittent, intense exposure increasing risk more than cumulative exposure. Some genetic disorders, such as nevoid BCC syndrome, predispose to BCC development as well. Typically, BCCs exhibit an indolent growth pattern with local invasion and tissue destruction over time, but metastasis is extremely rare. Nearly all BCCs have aberrant hedgehog pathway signaling, which leads to persistent activation and uncontrolled proliferation of basal cells (Iwasaki et al., 2012).

**Targeted Therapies for Cutaneous T-Cell Lymphoma**

**Denileukin diftitox** is a fusion protein composed of diphtheria toxin fragments A and B linked to the receptor-binding portion of IL-2. It is approved for treatment of advanced CTCL in patients with more than 20% of T cells expressing the surface marker CD25 (a subunit of the IL-2R), but it is not currently commercially available (Jawed et al., 2014).

The IL-2R is present on malignant and activated T cells but not resting B and T cells. Following binding to the IL-2R, denileukin diftitox is internalized by endocytosis. The active fragment of diphtheria toxin is then released into the cytosol, where it inhibits protein synthesis via ADP ribosylation of elongation factor-2 (EF-2), leading to cell death. The response rate is 30%. Adverse effects include pain, fevers, chills, nausea, vomiting, and diarrhea; immediate hypersensitivity reaction in 60% of patients; and capillary leak syndrome in 20%–30% of patients.

**Histone deacetylase inhibitors** approved for treatment of progressive, persistent, or recurrent CTCL refractory to other systemic therapies include vorinostat and romidepsin. The exact mechanism of antineoplastic effect is not fully characterized; however, inhibition of HDAC may restore expression of tumor suppressor or cell cycle regulatory genes with resultant cell cycle arrest, differentiation, and apoptosis of cancer cells (Jawed et al., 2014). The partial response rate is approximately 30%–35%, with uncommon complete response. The most common side effects are GI symptoms, fatigue, and hematologic abnormalities.

**Alentuzumab** is a humanized monoclonal antibody directed against CD52, which is found on immune cells, including T and B cells. Binding of alemtuzumab to CD52 causes neutrophil-mediated, antibody-dependent cellular toxicity (Jawed et al., 2014). It has been effectively used for the treatment of CTCL and may be a secondary treatment option for patients with CTCL refractory to other therapies. It is commonly associated with infusion reactions and causes prolonged immunosuppression. Early studies reported opportunistic infections, so antimicrobial prophylaxis is recommended.

**Targeted Therapies for Melanoma**

Until recently, therapies for metastatic melanoma had low response rates along with either high toxicity or no effect on long-term survival. There has been rapid development of several new therapeutic options for metastatic or unresectable melanoma, primarily geared toward inhibition of mutated, abnormally activated tyrosine kinases that drive growth or enhancing immune function to combat malignant cells by
inhibiting immune checkpoints (John and Cowey, 2015). These therapies include BRAF inhibitors (vemurafenib, dabrafenib), MEK inhibitors (trametinib), CTLA4 inhibitors (ipilimumab), and programmed death-1 inhibitors (pembrolizumab, nivolumab). These targeted treatments are discussed further in Chapter 67. An additional novel therapy for unresectable melanoma is talimogene laherparepvec (T-Vec), an oncolytic immunotherapy derived from genetically modified attenuated HSV type 1. It is administered by intralesional injection and is designed to selectively replicate within tumors and produce GM-CSF to enhance systemic antitumor immune responses. Talimogene is contraindicated in pregnancy and in immunosuppressed patients.

Treatment of Pruritus

Pruritus (itching) occurs in a multitude of dermatological disorders, including xerosis (dry skin), atopic dermatitis, urticaria, and infestations. Itching also may be a sign of internal disorders, including malignant neoplasms, chronic renal failure, and hepatobiliary disease. In addition to treating the underlying disorder, a general approach to the treatment of pruritus can be made by classifying pruritus into one of four clinical categories (Table 70–11).

### Drugs for Hyperkeratotic Disorders

Keratolytic agents reduce hyperkeratosis through myriad mechanisms (e.g., breaking of intercellular junctions, increasing stratum corneum water content, increasing desquamation). Common disorders treated with keratolytics include psoriasis, seborrheic dermatitis, xerosis, ichthyoses, and verrucae.

**α-Hydroxy acids** can reduce the thickness of the stratum corneum by solubilizing components of the desmosome, activating endogenous hydrolytic enzymes, and drawing water into the stratum corneum, thereby facilitating cell separation. They also appear to increase glycocosaminoglycans, collagen, and elastic fibers in the dermis and are used in various formulations to reverse photoaging. The FDA requires that cosmetics containing α-hydroxy acids be labeled with a sunburn alert warning that the product may increase sensitivity to the sun. α-Hydroxy acids used include glycolic, lactic, malic, citric, hydroxyacrylic, hydroxyacrylic, and mandelic.

**Salicylic acid** functions through solubilization of intercellular “cement,” reducing keratinocyte adhesion, and softening the stratum corneum. Salicycylism may occur with widespread and prolonged use, especially in children and patients with renal or hepatic impairment. Salicylate toxicity has been reported with application of as little as 1%-2% salicylic acid in neonates when applied multiple times per day over a large body surface area (Madan and Levitt, 2014). Salicylic acid, while chemically not a true β-hydroxy acid, often is listed as such on cosmetic labels. Other β-hydroxy acid ingredients in cosmetics include β-hydroxybutanoic acid, δ-tropic acid, and threohydroxycetic acid. Sun protection should accompany the topical application of these agents.

**Urea,** at low concentrations, increases skin absorption and retention of water, leading to increased flexibility and softness of the skin. At concentrations greater than 40%, urea denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

**Sulfur** is keratolytic, antiseptic, antiparasitic, and antiseborrheic. It exerts its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide (H₂S). H₂S breaks down keratin, causing dissolution of the stratum corneum.

**Propylene glycol** (as 60%-100% aqueous solutions) increases the water content of the stratum corneum and enhances desquamation. It is most effective in disorders with retention hyperkeratosis.

### Drugs Affecting Hair Growth

**Androgenic Alopecia**

Androgenetic alopecia, commonly known as male and female pattern baldness, is the most common cause of hair loss in adults older than 40 years. The frequency and severity increase with age and may begin during puberty in some patients. It is a genetically inherited trait with variable expression. In susceptible hair follicles, dihydrotestosterone (DHT) binds to the androgen receptor, and the hormone-receptor complex activates the genes responsible for the gradual transformation of large terminal follicles into miniaturized vellus follicles. Treatment of androgenetic alopecia is aimed at reducing hair loss and maintaining existing hair (Varothai and Bergfeld, 2014).

**Minoxidil,** originally developed as an antihypertensive agent (see Chapter 28), was noted to be associated with hypertrichosis in some patients. Topical minoxidil is available as a 2% solution and a 5% solution of water, leading to increased flexibility and softness of the skin. At concentrations greater than 40%, urea denatures and dissolves proteins and is used to dissolve calluses or avulse dystrophic nails.

**Sulfur** is keratolytic, antiseptic, antiparasitic, and antiseborrheic. It exerts its keratolytic effect by reacting with cysteine within keratinocytes, producing cystine and hydrogen sulfide (H₂S). H₂S breaks down keratin, causing dissolution of the stratum corneum.

**Propylene glycol** (as 60%-100% aqueous solutions) increases the water content of the stratum corneum and enhances desquamation. It is most effective in disorders with retention hyperkeratosis.
Finasteride inhibits the type II isozyme of 5α-reductase, the enzyme that converts testosterone to DHT (see Figure 45–3) and that is found in hair follicles. Balding areas of the scalp are associated with increased DHT levels and smaller hair follicles than nonbalding areas. Orally administered finasteride (1 mg/d) variably increases hair growth in men over a 2-year period. Finasteride is approved for use only in men but has been used off label for female pattern hair loss (Varothai and Bergfeld, 2014). Finasteride use in women is limited by its teratogenicity. Pregnant women should not be exposed to the drug because of the potential for inducing genital abnormalities in male fetuses. Adverse effects of finasteride include decreased libido, erectile dysfunction, ejaculation disorder, and decreased ejaculate volume. There have been postmarketing surveillance reports of persistent sexual dysfunction after stopping the medication. As with minoxidil, new hair growth will be lost when finasteride is discontinued.

Dutasteride (0.5 mg/day) is a combined type I and type II isozyme 5α-reductase inhibitor that has similar or greater efficacy, but side effects may be more common (Varothai and Bergfeld, 2014).

Spironolactone is an aldosterone antagonist and K+-sparring diuretic; it also has antihormone activity. It is used off label for female pattern alopecia at dosages of 50–200 mg/d (Varothai and Bergfeld, 2014). Women of reproductive potential should not receive spironolactone without reliable contraception because spironolactone can cause feminization of a male fetus.

Other Agents

Eflornithine is an ornithine decarboxylase (ODC) inhibitor approved for the reduction of excessive and unwanted facial hair in women. ODC is the rate-limiting enzyme in the synthesis of polyamines, which are important in cellular migration, differentiation, and proliferation. Levels of ODC activity are higher in proliferating cells, such as in follicular matrix cells in anagen phase, and inhibiting ODC decreases hair growth. Eflornithine 13.9% cream is applied twice daily and is intended to be used along with the patient’s preferred hair removal method to slow hair regrowth.

Bimatoprost is a prostaglandin analogue approved for topical treatment of hypotrichosis of the eyelashes by increasing their growth, including length, thickness, and darkness. The prostaglandin-mediated increase in eyelash growth was serendipitously noted during the use of intraocular prostaglandin analogues for glaucoma. The proposed mechanism of eye-lash growth is by an increase in the fraction of hairs in anagen, and the duration of the anagen phase. Increased pigmentation of the hairs is thought to occur due to stimulation of melanin production without an increase in the number of melanocytes. Importantly, brown pigmentation of the iris and eyelid skin may occur, and the increased iris pigmentation may be permanent.

Treatment of Hyperpigmentation

The agents discussed are most effective on hormonally or light-induced pigmentation within the epidermis. They have limited efficacy on postinflammatory pigmentation within the dermis. Sun protection or avoidance is a vital component of any treatment regimen (Sheth and Pandya, 2011).

Hydroquinone (1,4-dihydroxybenzene) decreases melanocyte pigment production by inhibiting tyrosinase, the initial enzyme in the melanin biosynthetic pathway. In addition, it causes degradation of melanosomes and destruction of melanocytes by production of reactive oxygen radicals. Formulations containing 1.5%–2% hydroquinone are available OTC; 3%–4% hydroquinone formulations are available by prescription. Pénétration enhancers and sunscreen ingredients are added to some formulations. A combination prescription product consisting of hydroquinone 4%, fluocinolone 0.01%, and tretinoin 0.05% is available. Adverse effects and contraindications include dermatitis and ochronosis.

Mequinol (4-hydroxyanisole) is a competitive inhibitor of tyrosinase. It was approved as a 2% prescription product in combination with 0.01% tretinoin and vitamin C for skin lightening, but it is not currently commercially available.

Monobenzene (monobenzyl ether of hydroquinone) causes permanent depigmentation and should not be used for routine hormonally induced or postinflammatory hyperpigmentation. A 20% cream is approved for final depigmentation therapy of extensive vitiligo affecting at least more than 50% body surface area; it is rarely used and not currently commercially available.

Glycolic acid is an α-hydroxy acid used in chemical peels for disorders of pigmentation. It is thought to work by inhibiting tyrosinase in a pH-independent manner and to cause exfoliation by decreasing keratinocyte adhesion. Potential side effects are erythema, desquamation, and postinflammatory hyperpigmentation. Glycolic acid peels are best used as adjunctive therapy along with other topical therapy in patients with refractory epidermal hyperpigmentation (Sheth and Pandya, 2011).

Miscellaneous Agents

Capsaicin is an alkaloid derived from plants of the Solanaceae family (i.e., hot chili peppers). Capsaicin interacts with the transient receptor potential vanilloid (TRPV1) receptor on C-fiber sensory neurons. TRPV1 is a ligand-gated nonselective cation channel of the TRP family, modulated by a variety of noxious stimuli. Chronic exposure to capsaicin first stimulates and then desensitizes this channel to capsaicin and diverse other noxious stimuli. Capsaicin also causes local depletion of substance P, an endogenous neuropeptide involved in sensory perception and pain transmission. Capsaicin (cream, lotion, gel, roll-on, and transdermal patch) is FDA approved for the temporary relief of minor aches and pains associated with backache, strains, and arthritis. It is also approved in patch form by prescription for postherpetic neuralgia and is used for off-label treatment of painful diabetic neuropathy and other forms of pruritus.

Bentoquatam (quaternium-18 benzotinate) is a mixture of quaternium-18 (quaternary ammonium chloride salts made from the fatty acids of tallow) and bentonite clay. This organoclay mixture is approved for OTC use as a topical barrier to prevent allergic contact dermatitis to the urushiol resin of poison ivy, oak, or sumac. The 5% topical lotion must be applied prophylactically at least 15 min prior to potential risk for exposure to urushiol and reapplied every 4 h.

Coal tar is a distillation product from coal, a mixture of over 10,000 compounds. It is used in dermatology primarily for the treatment of inflammatory skin conditions such as psoriasis, seborrheic dermatitis, and atopic dermatitis or other forms of eczematous dermatitis. The mechanism of action is unknown although it is known to suppress DNA synthesis. Coal tar has anti-inflammatory, antimicrobial, and antipruritic activity. In addition, it has a photosensitizing effect within the UVA and visible light spectrum between wavelengths of 330 and 550 nm. Multiple formulations and products are available commercially or through compounding, including those containing crude coal tar, coal tar extracts, or coal tar solution (Sandhu and Schwartz, 2011). Coal tar solution, also known as liquor carbonis detergens (LCD), is an alcohol extract of coal tar emulsified with polysorbate 80 to yield a more cosmetically acceptable product. Coal tar may be used in combination with UVB phototherapy (e.g., Goeckerman regimen), topical salicylic acid, or topical corticosteroids. Coal tar products are often poorly tolerated by patients due to its unpleasant odor, messiness, and potential for staining of clothing. It can also cause folliculitis or irritant contact dermatitis. Though occupational exposures to coal tar have been associated with malignancies (e.g., scrotal cancer), patients with psoriasis or atopic dermatitis who are treated with topical coal tar products have not exhibited increased risk of cancer (Menter et al., 2009a).

Anthralin (dithranol), a synthetic version of chrysoarbin, is derived from the bark of the Brazilian araroba tree and is used in the treatment of psoriasis and alopecia areata; its mechanisms of action are unclear (Menter et al., 2009a). Use of anthralin has been limited by the potential to cause irritant contact dermatitis and to stain skin, hair, nails, fabrics, and household items.
Brimonidine (0.33% topical gel) is an α₂ adrenergic agonist approved for once-daily treatment of persistent erythema of rosacea. It causes temporary vasoconstriction, and rebound erythema has been reported. α₁ Adrenergic agonists such as oxymetazoline have been used off label topically for erythematotelangiectatic rosacea as well.

Propranolol and timolol are nonselective β adrenergic antagonists traditionally used for cardiovascular disease. These agents are also effective in treating infantile hemangiomas and become the preferred treatment of infantile hemangiomas requiring intervention (Chen et al., 2013). Topical timolol drops and gel-forming solution are available but do not adequately treat deeper lesions.

Acknowledgment: Eric L. Wyatt, Steven H. Sutter, Lynn A. Drake, Lindy P. Fox, Hans F. Merk, David R. Bickers, and Lowell Goldsmith have contributed to this chapter in earlier editions of this book. We have retained some of their text in the current edition.

| Cyclosporine | • Psoriasis<br>• Off label for multiple inflammatory dermatoses | • MOA: calcineurin inhibition<br>• Potential side effects: hypertension, renal dysfunction, hypertrichosis, gingival hyperplasia, tremor |
### Systemic Cytotoxic, Immunosuppressant, and Immunomodulatory Agents (continued)

| mTOR inhibitors | MOA: mTOR inhibition | Potential side effects: stomatitis, mucositis, inflammatory cutaneous eruptions, nail changes |
|———|———|———|
| Off-label use in tuberous sclerosis, complex vascular malformations, and inflammatory dermatoses |

| Dapsone | MOA: mTOR inhibition | Potential side effects: stomatitis, mucositis, inflammatory cutaneous eruptions, nail changes |
|———|———|———|
| Dermatitis herpetiformis |
| Leprosy |
| Neutrophilic dermatoses (off label) |

| Thalidomide | MOA: mTOR inhibition | Potential side effects: stomatitis, mucositis, inflammatory cutaneous eruptions, nail changes |
|———|———|———|
| Erythema nodosum leprosum |
| Off label for prurigo nodularis, cutaneous lupus erythematosus, Behçet disease |

### Topical or Intraleosional Cytotoxic, Immunosuppressant, and Immunomodulatory Agents

| 5-Fluorouracil | MOA: microtubule inhibition to cause mitotic arrest in metaphase | Side effects: irritation and ulcerative local reactions |
|———|———|———|
| Actinic keratoses |
| Superficial basal cell carcinoma |
| Warts (off label) |

| Bleomycin | MOA: microtubule inhibition to cause mitotic arrest in metaphase | Side effects: irritation and ulcerative local reactions |
|———|———|———|
| Squamous basal cell carcinoma |
| Warts (off label) |

| Alkylating agents |
|———|
| Carmustine |
| Mechlorethamine |

| Podophyllum resin and podoflox | MOA: mitochondrial swelling and apoptosis of dysplastic keratinocytes |
|———|———|
| Genital warts |

| Ingenol mebutate | MOA: activates TLR-7, inducing cytokines and upregulating immune response | Potential local skin reaction or systemic flu-like symptoms |
|———|———|———|
| Genital warts |

| Imiquimod | MOA: activates TLR-7, inducing cytokines and upregulating immune response | Potential local skin reaction or systemic flu-like symptoms |
|———|———|———|
| Genital warts |
| Actinic keratoses |
| Superficial basal cell carcinoma |

| Sinecatechins | MOA: uncertain |
|———|———|
| Genital warts |

| mTOR inhibitors | MOA: not currently commercially available but may be compounded |
|———|———|
| Off-label use in tuberous sclerosis, complex vascular malformations, and some inflammatory dermatoses |

| Topical calcineurin inhibitors |
|———|
| Pimecrolimus |
| Tacrolimus |

| TNF-α inhibitors; IL-12/23 inhibitors; IL-17 inhibitors; PDE4 inhibitors; Jak inhibitors | MOA: Decreased T-cell activation | No skin atrophy | Useful in sensitive areas such as face and skinfolds | Common application site reactions (e.g., burning) decreases with continued use |
|———|———|———|———|———|
| Psoriasis |
| Atopic dermatitis; off-label use of PDE4 inhibitors, Jak inhibitors |

| Targeted Antineoplastic Agents |
|———|
| Smoothened inhibitors |
| Histone deacetylase inhibitors |
| BRAF inhibitors; MEK inhibitors; CTLA4 inhibitors; programmed death 1 inhibitors |

| Topical Agents for Hyperkeratotic Disorders |
|———|
| Alpha-hydroxy acids |
| Glycolic acid |
| Lactic acid |
| Salicylic acid |
| Urea |
| Sulfur |

| Alpha-hydroxy acids |
|———|
| Hyperkeratotic disorders |
| MOA: reduced keratinocyte adhesion by promoting degradation of comedonesomesomes |
| Potential skin irritation |

| Glycolic acid |
|———|
| Hyperkeratotic disorders |
| MOA: reduced keratinocyte adhesion by affecting desmosomal adhesion proteins |
| Potential skin irritation |
| Potential salicylate toxicity with heavy use |

| Lactic acid |
|———|
| Hyperkeratotic disorders |
| MOA: increased hydration of stratum corneum, enhancing desquamation |
| Potential skin irritation |

| Salicylic acid |
|———|
| Hyperkeratotic disorders |
| MOA: possibly through interaction with cysteine, causing reduction to hydrogen sulfide, which may break down keratin |
| Pungent odor |

| Urea |
|———|
| Hyperkeratotic disorders |
| MOA: possibly through interaction with cysteine, causing reduction to hydrogen sulfide, which may break down keratin |
| Pungent odor |

| Sulfur |
|———|
| Hyperkeratotic disorders |
| MOA: possibly through interaction with cysteine, causing reduction to hydrogen sulfide, which may break down keratin |
| Pungent odor |

Suggested Reading

Humans are exposed to chemicals from their environment daily. Fortunately, mammals have evolved mechanisms to protect themselves from toxic effects of many exogenous chemicals, including the xenobiotic transport and metabolic mechanisms described in Chapters 4–7. While the human body is relatively well adapted to deal with xenobiotics, there are situations in which such environmental agents may cause significant toxicity. The industrial revolution and the development of chemical industries have increased human exposures to chemicals that were previously infrequent or absent. Concern about environmental toxicants has stimulated interest and research in environmental toxicology, the study of how chemicals in our environment adversely affect human health; and in occupational toxicology, the study of how chemicals in the workplace affect human health. Many authoritative textbooks are available in these areas. This chapter does not attempt a thorough coverage; rather, it sets forth a few basic principles, briefly discusses carcinogens and chemoprevention, and then focuses on the pharmacotherapy of heavy metal intoxication.

### Assessment and Management of Environmental Risk

Environmental exposures to xenobiotics involve large populations exposed to many toxicants at low doses over long periods of time, which poses challenges for assessing the risks from those exposures. Thus, the focus of environmental risk assessment is on the low end of the dose-response curve, using experiments based on chronic exposures. Unlike drugs, which are given to treat a specific disease and should have benefits that outweigh the risks, environmental toxicants are usually only harmful. In addition, exposures to environmental toxicants usually are involuntary, there is uncertainty about the severity of their effects, and people are much less willing to accept their associated risks.

*Epidemiology* and *toxicology* provide complimentary approaches to predict the toxic effects of environmental exposures. Epidemiologists monitor health effects in humans and use statistics to associate those effects with exposure to an environmental stress, such as a toxicant. Toxicologists perform laboratory studies to examine potential toxic mechanisms of a chemical and to predict whether it is likely to be toxic to humans. Each of these approaches has strengths and weaknesses, and information from both is integrated into environmental risk assessment. Risk assessment is used to develop management approaches, such as laws and regulations, to limit exposures to environmental toxicants to a level that is considered safe.

### Epidemiological Approaches to Risk Assessment

Epidemiologists use a variety of study designs to look for statistical associations between environmental exposures, including chemical exposures, and health outcomes. This approach has the advantage of examining the effects of real-world exposures to humans but can be expensive and subject to biases and confounding effects.

#### Epidemiological Studies

Several types of epidemiological studies are used to assess risks, each with its own set of strengths and weaknesses.

- **Ecological studies** correlate frequencies of exposures and health outcomes between different geographical regions. These studies are inexpensive and are effective for generating hypotheses but are subject to confounders and are not effective for establishing causality.
- **Cross-sectional studies** examine the prevalence of exposures and outcomes at a single point in time. Such studies are an inexpensive way to determine an association but do not provide a temporal relationship and are not effective for establishing causality. They also can be subject to bias, as a health outcome under study might cause someone to eliminate his or her exposure.
- **Case-control studies** start with a group of individuals affected by a disease; this group then is matched to another group of unaffected individuals for known confounding variables. Questionnaires often are used to evaluate past exposures. This method also is relatively inexpensive and is good for examining rare outcomes because the end point is known. However, case-control studies rely on assessments of past exposures, which can be unreliable and subject to bias.
- **Cohort studies** measure exposures in a large group of people and follow that group for a long time to measure health outcomes. These studies are not as susceptible to bias and are better than case-control studies at establishing causality. However, they are expensive, particularly when measuring rare outcomes, because a large study population is required to observe sufficient disease to obtain statistical significance.
Abbreviations

ARE: antioxidant response element
ATSDR: Agency for Toxic Substances Disease Registry
BAL: British anti-Lewisite (dimercaprol)
BLL: blood lead level
CaNa₂ EDTA: calcium disodium ethylenediaminetetraacetic acid

MMA: monomethylarsenic
NOAEL: no adverse effect level
NOx: nitrogen oxides
NQO1: quinone reductase
NTP: National Toxicology Program
PG: prostaglandin
RfD: reference dose
ROS: reactive oxygen species
SC: subcutaneous

Biomarkers

Because of the difficulties in assessing human exposures and the long times required to clinically observe effects on health, epidemiologists often rely on biomarkers in risk assessment. Different types of biomarkers provide different information useful for risk assessment. Biomarkers aim to be specific, only detecting the change in affected individuals, and sensitive, detecting the change in all affected individuals.

- Clinical trials (see Chapter 1) cannot be used to directly measure the effects of environmental toxicants (for obvious ethical reasons) but can be used to examine the effectiveness of an interventional strategy for reducing both exposures and disease.

- Biomarkers of exposure provide information about dose or duration of exposures. Blood and urine concentrations of a chemical or its metabolite measure recent exposures, while levels in hair and toenails can measure exposure over a period of months. An example of an unusual exposure biomarker is X-ray fluorescent measurement of bone lead levels, which estimates lifetime exposure to lead.

- Biomarkers of toxicity are used to measure toxic effects at a subclinical level. Examples include measurement of liver enzymes in serum, changes in the quantity or contents of urine, and performance on specialized exams for neurological or cognitive function.

- Biomarkers of susceptibility are used to predict which individuals are likely to develop toxicity in response to a given chemical. Examples include single-nucleotide polymorphisms in genes for metabolizing enzymes involved in the activation or detoxification of a toxicant.

- Some biomarkers simultaneously provide information on exposure, toxicity, or susceptibility. For example, the measurement in the urine of N7-guanine adducts from aflatoxin B₁ provides evidence of both exposure and a toxic effect (in this case, DNA damage).

Toxicological Approaches to Risk Assessment

Toxicologists use model systems, including experimental animals, to examine the toxicity of chemicals and predict their effects on humans. Toxicologists typically must test chemicals at higher doses than would be observed in the environment to see enough occurrences of a toxic outcome to obtain statistical significance. As a result, there is often uncertainty about the effects of very low doses of chemicals. To determine the applicability of model systems, toxicologists also study the mechanisms involved in the toxic effects of chemicals, with the goal of predicting whether that mechanism would occur in humans.

To predict the toxic effects of environmental chemicals, toxicologists perform subchronic studies (3 months of treatment for rodents) and chronic studies (2 years for rodents) in at least two different animal models. Doses for these studies are based on shorter preliminary studies, with the goal of having one concentration that does not have a significant effect, one concentration that results in statistically significant toxicity at the low end of the dose-response curve, and one or more concentrations that will have moderate-to-high levels of toxicity. A theoretical dose-response curve for an animal study is shown in Figure 71–1.

An animal study provides two numbers that estimate the risk from a chemical:

- The NOAEL is the highest dose used that does not result in a statistically significant increase in negative health outcomes.
- The LOAEL is the lowest dose that results in a significant increase in toxicity.

The NOAEL is divided by 10 for each source of uncertainty to determine a RID, which is commonly used as a starting point for determining regulations on human exposures to chemicals. The modifiers used to determine the RID are based on the uncertainties between experimental and human exposure. The most common modifiers used are for interspecies variability (human to animal) and interindividual variability (human to human), in which case RID = NOAEL/100. Other modifiers can be used to account for specific experimental uncertainties, such as the unavailability of data from chronic studies. The use of factors of 10 in the denominator for determination of RID is an application of the “precautionary principle,” which attempts to limit human exposure by assuming a worst-case scenario for each unknown variable.

A major concern with animal studies is that they do not detect effects at low concentrations. Typically, they are designed to obtain statistical significance with a 10%–15% increase in an outcome. As a result, there is considerable uncertainty about what occurs below that level, as demonstrated in Figure 71–1. Toxicologists often assume that there is a threshold dose below which there is no toxicity. However, the shape of the dose-response curve below the NOAEL is not known with certainty and represents a point of departure (POD). The existence of a threshold dose assumes that there are cellular defenses that prevent toxicity at concentrations below a given level, and that they can be overwhelmed. Some carcinogens may not exhibit a threshold, while others for which defense mechanisms exist do and other toxicants with specific molecular targets (e.g., lead) do not exhibit a threshold. Ideally, mechanistic studies should be done to predict which dose-response curve is most likely to fit a given chemical.

Toxicologists perform mechanistic studies to understand how a chemical might cause toxicity. Computer modeling using a compound’s three-dimensional structure to determine quantitative structure-activity relationships (QSAR) is commonly performed on both drugs and environmental chemicals. QSAR approaches can determine which chemicals are likely to exhibit toxicities or bind to specific molecular targets. Cell-based approaches in prokaryotes and eukaryotes are used to determine whether a compound damages DNA or causes cytotoxicity. DNA damage and the resulting mutagenesis often are determined with the Ames test, which uses Salmonella typhimurium strains with specific mutations in the gene needed to synthesize histidine. These strains are treated with chemicals in the presence or absence of a metabolic activating system (usually hepatic xenobiotic metabolizing enzymes). If a compound is a
Carcinogenesis and Chemoprevention

Carcinogenesis

The IARC classifies the carcinogenicity of compounds into groups based on risk assessments using epidemiologic, human exposure, animal, and mechanistic data. Chemicals in group 1 are known human carcinogens; group 2A are chemicals that are probably carcinogenic in humans; group 2B are chemicals that are possibly carcinogenic in humans; group 3 are chemicals for which data are lacking to suggest a role in carcinogenesis; and group 4 are those for which the data indicate that they are unlikely to be carcinogens. Table 71–1 provides examples of group 1 carcinogens.

The transformation of a normal cell to a malignancy is a multistage process, and exogenous chemicals can act at one or more of these stages. A classic model of chemical carcinogenesis is tumor initiation followed by tumor promotion. In this model, an initiator causes gene mutations that can occur through sustained transcription or silencing of a gene. These chemicals can increase the absorption or change the metabolism of other chemicals, increasing the probability that they form active metabolites in target tissues. They can also interfere with DNA repair, increasing the occurrence of mutations from a second genotoxic carcinogen. For example, ethanol acts as a solvent and increases the absorption of tobacco carcinogens, increasing the risk of head and neck cancers in people who both smoke and drink. Ethanol also depletes GSH, limiting target cells’ ability to detoxify reactive metabolites of carcinogens and ROS.

Chemoprevention

Drugs that interfere with the carcinogenic process to prevent cancer before it is diagnosed are termed chemopreventive agents (Szabo, 2006;...

William et al., 2009). The chemoprevention concept was pioneered during the 1960s by Wattenberg and others, who observed that dietary constituents, such as β-carotene, could prevent cancer in rodents (Wattenberg, 1966). Chemoprevention strategies often are based on epidemiological studies on nutrition, where there are many examples of clear protective effects of plant-based foods and drinks on the incidence of various types of cancer (Fahey and Kensler, 2007). By isolating the active compounds from protective plants, researchers hope to understand their protective mechanisms and develop drugs to prevent cancer. Chemoprevention is an emerging field; a number of compounds for the prevention of cancer are in clinical trials (Table 71–2). Most chemicals tested for chemoprevention have not exhibited a benefit, and in some cases they have increased the risk of cancer (Potter, 2014). There are currently no drugs approved for chemoprevention of environmental carcinogenesis, but there are approved drugs to prevent carcinogenesis due to endogenous estrogen (tamoxifen and raloxifene) and viruses (hepatitis B and human papillomavirus vaccines).

Chemopreventive agents can interfere with initiation or promotion (Figure 71–2). One mechanism of anti-initiation is prevention of carcinogen activation. Isothiocyanates inhibit CYPs involved in activating many carcinogens and also upregulate genes controlled by the antioxidant response element (ARE); the ARE-responsive genes include γ-glutamylcysteine synthase light chain (which catalyzes the rate-determining step in GSH synthesis) and quinone reductase. Increased expression of ARE-regulated genes is predicted to increase the detoxification of proximate carcinogens. Isothiocyanates also stimulate apoptosis of p53-deficient cells via the formation of cytotoxic DNA adducts.

Compounds that act as antioxidants may provide protection because many carcinogens work through the generation of ROS. Some compounds simultaneously prevent carcinogen activation and act as antioxidants.

---

Figure 71–2 Carcinogenesis: initiation and promotion. There are multiple steps that occur between the exposure to a genotoxic carcinogen and the development of cancer. Processes in red lead to the development of cancer, while those in green reduce the risk. Nongenotoxic carcinogens act by enhancing steps leading to cancer or inhibiting protective processes. A chemopreventive agent acts by inhibiting steps leading to cancer or by increasing protective processes.

</table>

For example, flavonoids and other polyphenols found in a wide variety of plants are potent antioxidants that also inhibit CYPs and induce expression of ARE-regulated genes. Chlorophyll and other compounds can protect against carcinogens by binding to or reacting with carcinogens or their metabolites and preventing them from reaching their molecular target.

Inflammation is a potential target for chemoprevention through interference with promotion. In phase 3 studies, the COX-2 inhibitor celecoxib demonstrated efficacy at reducing the risk of colorectal cancer. However, this benefit was offset by an increased risk of death due to cardiovascular events, forcing the early termination of the trial (William et al., 2009). Studies examining long-term treatment with aspirin for cardiovascular benefits found that aspirin also reduces the incidence of colorectal adenomas and overall cancer mortality. A phase 3 clinical trial is under way to examine this effect. Naturally occurring compounds such as α-tocopherol have also been hypothesized to exert chemoprevention by reducing inflammation. However, α-tocopherol actually increased the risk of prostate cancer in a phase 3 trial (Potter, 2014).

Another approach to chemoprevention is disruption of nuclear receptor signaling. Retinoids reduce the incidence of head and neck cancers, and is one of the first successful uses of chemoprevention in humans (Evans and Kaye, 1999; William et al., 2009). Retinoids are also effective for the treatment for acute promyelocytic leukemia (see Section VII). However, in large clinical trials, retinoids increased the incidence of lung cancer, particularly amongst women, and had other unacceptable toxicities (Omenn et al., 1996).

The selective ER modulators tamoxifen and raloxifene reduced the incidence of breast cancer in high-risk women in large phase 3 clinical trials and are approved for chemoprevention in these patients (Vogel et al., 2006). The success of selective ER modulators for chemoprevention provides a proof-of-principle that the development of compounds based on mechanistic predictions of antipromotion activity can lead to effective drugs for the prevention of cancer.

### Aflatoxin B₁

Agents are being developed as chemopreventants of hepatocarcinogenesis mediated by aflatoxin B₁. Aflatoxins are produced in regions with hot and wet climates by *Aspergillus flavus*, a fungus that is a common contaminant of foods, especially corn, peanuts, cottonseed, and tree nuts. As a result of exposure to aflatoxin, human hepatocellular carcinoma is a serious problem in subtropical and tropical regions of Latin America, Africa, and Southeast Asia. Human exposure to aflatoxin in the U.S. is rare and not thought to have a significant impact on health (IARC, 2002).

### ADME

Aflatoxin B₁ is readily absorbed from the GI tract and initially distributed to the liver, where it undergoes extensive first-pass metabolism (Guengerich et al., 1996). Aflatoxin B₁ is metabolized by CYPs 1A2 and 3A4 to yield either an 8,9-epoxide or products hydroxylated at the 9 position (aflatoxin M₁) or 3 position (aflatoxin Q₂; Figure 71–3). While the hydroxylation products are detoxification products, the 8,9-epoxide reacts with DNA and is responsible for aflatoxin carcinogenesis. The 8,9-epoxide is short lived and undergoes detoxification via nonenzymatic hydrolysis or conjugation with GSH. Aflatoxin M₁ enters the circulation and is excreted in urine and milk.

### Toxicity

Aflatoxin B₁ primarily targets the liver, although it also is toxic to the GI tract and hematological system. High-dose exposures result in acute necrosis of the liver, leading to jaundice and, in many cases, death. Acute toxicity from aflatoxin is rare in humans and requires consumption of milligram quantities of aflatoxin per day for multiple weeks. Chronic exposure to aflatoxins results in cirrhosis of the liver and immunosuppression.

### Carcinogenicity

Based on increased incidence of hepatocellular carcinoma in humans exposed to aflatoxin and on supporting animal and mechanistic data,
Aflatoxin primarily forms DNA adducts at deoxyguanosine residues, reacting at either the N1 or N7 position (IARC, 2002). The 8,9-epoxide of aflatoxin B₁ readily reacts with amines. The N7-guanine adduct mispairs with adenine, leading to G → T transversions. Human aflatoxin exposure is associated with hepatocellular carcinomas bearing an AGG-to-AGT mutation in codon 249 of the p53 tumor suppressor gene, resulting in the replacement of an arginine with cysteine (Hussain et al., 2007). Several mechanisms for the synergistic interaction between hepatitis B and aflatoxin are under investigation (Sylla et al., 1999). The X gene of hepatitis B virus encodes a protein, HBx, that binds to and inhibits p53, resulting in suppressed nucleotide excision repair of aflatoxin B₁ adducts (Hussain et al., 2007). Hepatitis B also alters the metabolism of aflatoxin B₁ by upregulating CYP genes, including CYP3A4, and decreases GSH S-transferase activity. In addition, hepatocellular proliferation to repair damage done by hepatitis B infection increases the likelihood that aflatoxin-induced DNA adducts will cause mutations. The hepatotoxic and tumor-promoting effects of hepatitis B also could provide a more favorable environment for the proliferation and invasion of initiated cells.

**Chemoprevention of Aflatoxin-Induced Hepatocellular Carcinoma**

The relationship between aflatoxin metabolism and its carcinogenicity makes it an appealing target for chemopreventive strategies that modify its metabolism (Figure 71–3). Inhibiting CYP activity or increasing GSH conjugation will reduce the intracellular concentration of the 8,9-epoxide and prevent DNA adduct formation (Groopman et al., 2008; Kensler et al., 2004). Oltipraz, an antischistosomal drug, potently inhibits CYPs and induces genes regulated by the ARE that are involved in GSH synthesis. Oltipraz increases the excretion of the N-acetylcysteine aflatoxin conjugate, indicating enhanced GSH conjugation of the epoxide. At 500 mg/week, oltipraz reduced the levels of aflatoxin M₁, consistent with inhibition of CYP activity.

Green tea polyphenols (GTPs) also have been used to modify aflatoxin metabolism in exposed human populations. Individuals receiving a daily dose of 500 or 1000 mg (equivalent to 1 or 2 L of green tea) demonstrated a small decline in the formation of aflatoxin-albumin adducts and a large increase in the excretion of the N-acetylcysteine aflatoxin conjugate, consistent with a protective effect.

Another approach used for the chemoprevention of aflatoxin hepato-carcinogenesis is the use of “interceptor molecules.” Chlorophyllin, a mixture of water-soluble chlorophyll salts, binds tightly to aflatoxin in the GI tract, forming a complex that is not absorbed. In vitro, chlorophyllin inhibits CYP activity and acts as an antioxidant. In a phase 2 trial, administration of 100 mg of chlorophyllin with each meal reduced aflatoxin-N7-guanine adduct levels in the urine. Because of the strong interaction between hepatitis B and aflatoxin in carcinogenesis, the hepatitis B vaccine reduces the sensitivity of people to the induction of cancer by aflatoxin. Primary prevention of aflatoxin exposure through hand or fluorescent sorting of crops to remove those with fungal contamination also reduces human exposure. A cost-effective primary prevention approach is to improve food storage to limit the spread of Aspergillus flavus, which requires a warm and humid environment.

**Water and Air Pollution**

The U.S. EPA protects the public from water and airborne pollutants by enforcing compliance with the Clean Water Act (protects the public and the environment from water pollution); the Safe Drinking Water Act (ensures the quality of the drinking water); and the Clean Air Act (to protect the public from air pollutants). Under these laws, the EPA combines scientific risk assessment with economic analyses and other factors to develop regulations on the release or presence of specific pollutants to limit their effect on human health and the environment.

Toxicity screening of many water contaminants has led to the development of maximum contaminant levels (MCLs) for drinking water. To protect against potential adverse health effects, a primary MCL sets a level for a contaminant that must not be exceeded. The primary MCL is based on consideration of the toxic dose-response curve and on whether a sufficiently sensitive analytical method exists to measure the contaminant for compliance purposes. A secondary MCL is not enforced but is established for aesthetic value (e.g., taste, color, odor) that may not affect health. Currently, there is concern about pharmaceutical waste in the water supply, but MCLs have not been set for these compounds.

The EPA also monitors six priority air pollutants (CO, Pb, NOₓ, O₃, particulate matter, and SO₂) that they have determined play the largest role in human health effects from air pollution. The EPA sets National Ambient Air Quality Standards in which local levels of these pollutants may not be exceeded within a given time frame. Measurements made by stationary...
Metals are an important class of environmental toxicants; they are ubiquitous environmental contaminants that come from both natural and anthropogenic sources. The CDC lists arsenic, mercury, and lead as the top three pollutants of concern, based on their toxicity and levels of human exposure. Although the toxicity of high levels of exposure to metals has long been known, the effects of low-dose chronic exposure to metals have only recently been appreciated. Many of the toxic metals in the environment also are carcinogens (Table 71–3). In addition, several essential metals also are toxic under conditions of overdose. Copper and iron are associated with toxicities, primarily targeting the liver through generation of ROS.

Lead

Chronic exposure to very low levels of lead has major deleterious effects, particularly for children.

Exposure

Despite substantial improvements over the past four decades, lead exposure remains a major concern, especially for children. In the U.S., paint containing lead for use in and around households was banned in 1978, while the use of tetraethyl lead in gasoline was phased out between 1976 and 1996. Despite these bans, past use of lead carbonate and lead oxide in paint and tetraethyl lead in gasoline remain the primary sources of lead exposure. Lead is not degradable and remains in dust, soil, and the paint of older homes. Young children are exposed to lead by nibbling sweet-tasting paint chips or ingesting dust and soil in and around older homes. Renovation or demolition of older buildings may cause substantial lead exposure. Removal of lead from gasoline reduced lead levels in air by more than 90% between 1982 and 2002, but lead fallout from air pollution remains in soils, particularly in urban environments. Lead was also commonly used in plumbing and can leach into drinking water. Lead exposure also has been traced to other sources, such as inhalation of dusts and fumes at firing ranges, retained bullets, artists’ paint pigments, ashes and fumes from painted wood, lead-glazed pottery, lead toys, non-Western folk medicines, cosmetics, jewelers’ wastes, home battery manufacture, and lead type (ATSDR, 2007b). BLLs in children have steadily decreased since the 1970s, when the mean level was 15 μg/dL. Currently, the average BLL in children is at 1.3 μg/dL.

The CDC recently updated its recommendations to reflect the modern understanding that there is no safe level of lead exposure for children (CDC, 2012). The CDC no longer provides a “level of concern,” as any lead exposure to a child is concerning. Instead, the CDC emphasizes primary prevention of lead exposure in all children and recommends that children with a BLL that places them in the top 2.5% (currently ≥ 5 μg/dL) be identified as in need of exposure reduction and additional screening. They did not change the existing recommendation that physicians consider chelation therapy for children with a BLL above 45 μg/dL.

Occupational exposure to lead also has decreased because of protective regulations. Occupational exposure generally is through inhalation of lead-containing dust and lead fumes. Workers in lead smelters and storage battery factories are at the greatest risk for lead exposure. Other workers at risk for lead exposure are those associated with steel welding or cutting, construction, rubber and plastic industries, printing, firing ranges, radiator repair shops, and any industry where lead is flame soldered (ATSDR, 2007b).

Chemistry and Mode of Action

Lead exists in its metallic form and as divalent or tetravalent cations. Divalent lead is the primary environmental form; inorganic tetravalent lead compounds are not found naturally. Organo-lead complexes primarily occur with tetravalent lead and include the gasoline additive tetraethyl lead.

Lead toxicity results from molecular mimicry of other divalent metals (Garza et al., 2006), principally zinc and calcium. Because of its size and electron affinity, lead alters protein structure and can inappropriately activate or inhibit protein function.

ADME

Lead exposure occurs through ingestion or inhalation. GI absorption of lead varies considerably with age and diet. Children absorb a much higher percentage of ingested lead (~40% on average) than adults (<20%). Absorption of ingested lead is drastically increased by fasting. Dietary calcium or iron deficiencies increase lead absorption, suggesting that lead is absorbed through divergent metal transporters. The absorption of inhaled lead (~90%) generally is much more efficient than through dietary intake. Tetravalent lead is readily absorbed through the skin, but transdermal absorption does not occur with inorganic lead.

About 99% of lead in the bloodstream binds to hemoglobin. Lead initially distributes in the soft tissues, particularly in the tubular epithelium of the kidney and the liver. Over time, lead is redistributed and deposited in bone, teeth, and hair. About 95% of the adult body burden of lead is

*The ATSDR has both detailed monographs and brief summaries for each of these compounds (available at https://www.atsdr.cdc.gov). The IARC also has monographs available (http://monographs.iarc.fr).

Health Effects

Although the effects of high-dose lead poisoning have been known for more than 2000 years, the insidious toxicities of chronic low-dose lead poisoning (BLL < 20 µg/dL) have only recently been discovered. Lead is a nonspecific toxicant; the most sensitive systems are the nervous, hematological, cardiovascular, and renal systems (Table 71–4). Uncovering the effects of low-level lead exposure on complex health outcomes, such as neurobehavioral function and blood pressure, has been the subject of extensive research and the object of considerable public concern.

Neurotoxic Effects. The biggest concerns with low-level lead exposure are cognitive delays and behavior changes in children (ATSDR, 2007b; Bellinger and Bellinger, 2006). The developing nervous system is very sensitive to the toxic effects of lead, with effects persisting down to the lowest measurable levels of lead (Cranfield et al., 2003; Lanphear et al., 2005).

Lead neurotoxicity primarily results from inhibition of Ca\(^{2+}\) transporters and channels and altered activities of Ca\(^{2+}\) responsive proteins, including PKC and calmodulin (Bellinger and Bellinger, 2006; Garza et al., 2006). These actions limit the normal activation of neurons in response to Ca\(^{2+}\) release and cause inappropriate production or release of neurotransmitters. Lead affects multiple neurotransmitter pathways, including the dopaminergic, cholinergic, and glutaminergic systems. At high concentrations, lead causes disruption of membranes, including the blood-brain barrier, increasing their permeability to ions.

Lead alters brain development by interfering with the pruning of synapses, neuronal migration, and the interactions between neurons and glial cells. Neurotransmitter release and PKC signaling determine which synapses are maintained and which are lost during brain development; this process is disrupted by lead. Lead-induced alterations in brain development can result in decreased IQ, poor performance on exams, language and motor deficits, and behavioral problems such as distractibility, impulsivity, aggression, short attention span, and inability to follow simple sequences of instructions (ATSDR, 2007b; CDC, 2014). There is no evidence for a threshold; associations are evident even at the lowest measurable BLL (Figure 71–4). The cognitive and behavioral changes caused by lead vary considerably among children and may depend on the timing of exposure.

Children with very high BLL (>70 µg/dL) are at risk for encephalopathy. Symptoms of lead-induced encephalopathy include lethargy, vomiting, irritability, anorexia, and vertigo, which can progress to ataxia, delirium, and eventually coma and death. Mortality rates for lead-induced encephalopathy are about 25%, and most survivors develop long-term sequelae such as seizures and severe cognitive deficits.

Adults can also develop encephalopathy from lead exposure, although they are less sensitive than children. Workers chronically exposed to lead can develop neuromuscular deficits, termed lead palsy. Symptoms of lead palsy, including wrist drop and foot drop, were commonly associated with painters and other lead-exposed workers during previous eras but are rare today. Lead induces degeneration of motor neurons, usually without affecting sensory neurons. Studies in older adults have shown associations between lead exposure and decreased performance on cognitive function tests, suggesting that lead accelerates neurodegeneration due to aging (ATSDR, 2007b).

Figure 71–4: Effect of childhood lead exposure on IQ. Childhood exposure to lead shows a nonlinear dose-response relationship, with a steeper curve at low concentrations of lead (estimated dose-response curve based on data from Lanphear et al., 2005, and Canfield et al., 2003). For comparison, the average BLL from three iterations of the National Health and Nutritional Examination Survey are shown (Wheeler and Brown, 2013).
Cardiovascular and Renal Effects. Elevated blood pressure is a lasting effect of low-level lead exposure (BLL < 10 μg/dL). Adults who were exposed to lead during infancy and childhood have elevated blood pressure even in the absence of a recent exposure (ATSDR, 2007b). Lead exposure is associated with an increased risk of death due to cardiovascular and cerebrovascular disease (Schober et al., 2006).

In the kidney, low-level lead exposure (BLL < 10 μg/dL) depresses glomerular filtration. Higher levels (>30 μg/dL) cause proteinuria and impaired transport, while very high levels (>50 μg/dL) cause permanent physical damage, including proximal tubular nephropathy and glomerulosclerosis. Impaired glomerular filtration and elevated blood pressure are closely interrelated and likely have causative effects on one another (ATSDR, 2007b).

The cardiovascular effects of lead are thought to involve the production of ROS, which react with NO to prevent vasodilation (Vaziri and Khan, 2007). It is not known how lead reduces glomerular filtration rate, although there is evidence that lead targets kidney mitochondria and interferes with the electron transport chain (ATSDR, 2007b).

Other Effects. Lead causes both immunosuppression and increased inflammation, primarily through changes in helper T-cell and macrophage signaling; these effects can occur at low BLLs in children (Dietert and Piepenbrink, 2006). Lead inhibits the activity of several enzymes involved in the biosynthesis of heme; this effect persists down to very low BLL (<10 μg/dL; Figure 71–5). Chronic high-dose lead intoxication is associated with hypochromic microcytic anemia, which is observed more frequently in children and is morphologically similar to iron-deficient anemia. Acute high-dose lead exposure affects the smooth muscle of the gut, producing intestinal symptoms, termed lead colic.

Carcinogenesis. The IARC classifies lead in group 2A, “probably carcinogenic to humans” (IARC, 2006). Epidemiological studies show associations between lead exposure and cancers of the lung, brain, kidney, and stomach. Rodents exposed to lead develop kidney tumors, and some rats develop gliomas. Lead is not mutagenic but increases clastogenic events. Lead carcinogenesis may result from inhibition of DNA-binding zinc-finger proteins, including those involved in DNA repair and synthesis. Lead is a good example of a nongenotoxic carcinogen.

Mercury

Mercury is a unique metal in that it is a liquid at room temperature. Mercury has been used industrially since ancient Greece due to its capacity to amalgamate with other metals, and mercury’s toxicity was noted by Hippocrates. Mercury also was used as a therapeutic drug for several centuries. Its use for the treatment of syphilis inspired Paracelsus’s observation that “the dose makes the poison,” one of the central concepts of toxicology, and also gave rise to the cautionary expression: “A night with Venus, a year with Mercury.” The phrase “mad as a hatter” originated from the exposure of hatters to metallic mercury vapor during production of felt for hats using mercury nitrate. While the phrase likely inspired the character of the Mad Hatter in Alice in Wonderland, his symptoms are not consistent with mercury exposure.

Exposure

Inorganic mercury cations and metallic mercury are found in the Earth’s crust, and mercury vapor is released naturally into the environment through volcanic activity and off-gassing from soils. Mercury also enters the atmosphere through human activities, such as combustion of fossil fuels and gold mining. In 2011, the EPA set the first standards to reduce mercury emissions from coal-fired power plants. Once in the air, metallic mercury is photo-oxidized to inorganic mercury, which can then be deposited in aquatic environments in rain. Microorganisms can then conjugate inorganic mercury to form methyl mercury. Methyl mercury concentrates in muscle and other tissues and will bioaccumulate up the food chain (Figure 71–6). As a result, mercury concentrations in aquatic organisms at the top of the food chain, such as swordfish or sharks, are high (ATSDR, 1999).

The primary source of exposure to Hg⁰ in the general population is vaporization of Hg⁰ in dental amalgam. Human exposure to organic mercury primarily is through the consumption of fish. Other foods contain inorganic mercury at low levels (ATSDR, 1999).

Workers are exposed to Hg⁰ and inorganic mercury, most commonly through exposure to vapors. The highest risk for exposure is in the chloralkali industry (i.e., bleach) and in other chemical processes in which mercury is used as a catalyst. Mercury is a component of many devices, including alkaline batteries, fluorescent bulbs, thermometers, and scientific equipment, and exposure occurs during the production of these devices. Dentists also are exposed to Hg⁰ from amalgam. Hg⁰ can be used to extract gold during mining, which results in substantial occupational exposure. Mercuric salts are used as pigments in paints (ATSDR, 1999).

Thimerosal is an antimicrobial agent used as a preservative in some vaccines. Its use is controversial because it releases ethyl mercury, which is chemically similar to methyl mercury. Some parents have expressed concern that thimerosal might contribute to autism. Even though these concerns were based on a long-discredited report, the American Academy of Pediatrics and the U.S. Public Health Service issued a call for thimerosal’s replacement in vaccines to improve the prevalence of vaccination, and thimerosal was removed from childhood vaccines in 2001 (Ball et al., 2001). Concurrently, studies found no association between thimerosal use in vaccines and negative outcomes, and thimerosal is still used...
in influenza vaccines (Heron and Golding, 2004). The FDA maintains a list of the thimerosal content in vaccines (http://www.fda.gov/BiologicsBloodVaccines/SafetyAvailability/VaccineSafety/UCM096228).

**Chemistry and Mode of Action**

There are three general forms of mercury of concern to human health. Metallic, or elemental, mercury (Hg0) is the liquid metal found in scientific equipment and dental amalgam; it is volatile, and exposure is often to the vapor. Inorganic mercury can be either monovalent (mercurous, Hg+2) or divalent (mercuric, Hg+2) and forms a variety of salts. Organic mercury compounds consist of divalent mercury complexed with one or two alkyl groups. Methyl mercury (MeHg), which is formed environmentally from inorganic mercury by aquatic microorganisms, is of most concern. Both Hg+2 and MeHg readily form covalent bonds with sulfur, which causes most of the biological effects of mercury. At very low concentrations, mercury reacts with sulfhydryl residues on many proteins and disrupts their functions. Microtubules are particularly sensitive to the toxic effects of mercury, which disrupts their formation and can catalyze their disassembly (Clarkson, 2002). There also may be an autoimmune component to mercury toxicity.

**ADME**

The vapor of Hg0 is readily absorbed through the lungs (~70%–80%), but GI absorption of Hg0 is negligible. Once absorbed, Hg0 distributes throughout the body and crosses membranes, such as the blood-brain barrier and the placenta, via diffusion. Hg0 is oxidized by catalase in cells to form Hg+2. Shortly after exposure, some Hg+2 is eliminated in exhaled air. After a few hours, distribution and elimination of Hg0 resemble the properties of Hg+2. Hg0 vapor can be oxidized to Hg+2 in the brain and retained (ATSDR, 1999).

Gastrointestinal absorption of mercury salts varies depending on the individual and on the particular salt and averages about 10%–15%. Hg+2 will form Hg+3 or Hg2+ in the presence of sulfhydryl groups. Hg+1 is primarily excreted in the urine and feces; a small amount also can be reduced to Hg+0 and exhaled. With acute exposure, the fecal pathway predominates, but following chronic exposure, urinary excretion becomes more important. All forms of mercury also are excreted in sweat and breast milk and deposited in hair and nails. The t1/2 for inorganic mercury is approximately 1–2 months (ATSDR, 1999).

Complexes between MeHg+ and cysteine resemble methionine and can be recognized by transporters for that amino acid and taken across membranes (Ballatori, 2002). Orally ingested MeHg+ is almost completely absorbed from the GI tract. MeHg+ readily crosses the blood-brain barrier and the placenta and distributes fairly evenly to the tissues, although concentrations are highest in the kidneys (ATSDR, 1999). MeHg+ can be demethylated to form inorganic Hg+2. The liver and kidney exhibit the highest rates of demethylation, but this also occurs in the brain. MeHg+ is excreted in the urine and feces, with the fecal pathway dominating. The t1/2 for MeHg+ is about 2 months. The toxicodynamic properties of MeHg+ are thought to result from molecular mimicry.

**Health Effects**

**Metallic Mercury.** Inhalation of high levels of Hg0 vapor over a short duration is acutely toxic to the lung. Respiratory symptoms of Hg0 exposure start with cough and tightness in the chest and can progress to interstitial pneumonitis and severely compromised respiratory function. Other initial symptoms include weakness, chills, metallic taste, nausea, vomiting, diarrhea, and dyspnea. Acute exposure to high doses of Hg0 is also toxic to the CNS, with symptoms similar to those of chronic exposure (Figure 71–7).

Toxicity to the nervous system is the primary concern with chronic exposure to Hg0. Symptoms include tremors (particularly of the hands); emotional lability (irritability, shyness, loss of confidence, and nervousness); insomnia; memory loss; muscular atrophy; weakness; paresthesia; and cognitive deficits. These symptoms intensify and become irreversible with increases in duration and concentration of exposure. Other common symptoms of chronic mercury exposure include kidney damage, tachycardia, palpitations, severe salivation, and gingivitis.

**Inorganic Salts of Mercury.** Ingestion of Hg+2 salts is intensely irritating to the GI tract, leading to vomiting, diarrhea, and abdominal pain. Acute exposure to Hg+2 or Hg+2 salts (typically in suicide attempts) leads to renal tubular necrosis, resulting in decreased urine output and often acute renal failure. Chronic exposures also target the kidney, with glomerular injury predominating.

**Organic Mercury.** The CNS is the primary target of MeHg+ toxicity. Symptoms of high-dose MeHg+ exposure include visual disturbances, ataxia, paresthesia, fatigue, hearing loss, slurring of speech, cognitive deficits, muscle tremor, movement disorders, and, following severe exposure, paralysis and death. The developing nervous system exhibits increased sensitivity to MeHg+. Children exposed in utero can develop severe symptoms, including mental retardation and neuromuscular deficits, even in
Arsenic can enter the environment through natural processes or human activities. In the U.S., the levels of arsenic in drinking water average 2 μg/L (ppb). However, in some parts of the world, particularly Taiwan, China, Argentina, Chile, Bangladesh, and eastern India, the levels of arsenic in drinking water can exceed 50 μg/L, which is five times the MCL set by the EPA (Mead, 2005).

The absorption of arsenic compounds is directly related to their solubility. Poorly water-soluble compounds such as arsenic sulfide, lead arsenate, and galena are less likely to be absorbed by the body. Inorganic arsenic compounds, such as arsenic trioxide, are more likely to be absorbed and can cause significant toxicity. Arsenic is in the production and use of organic arsenicals as herbicides, insecticides, and metal preservatives.

Inorganic arsenic compounds, such as arsenic trioxide, are more likely to be absorbed and can cause significant toxicity. Arsenic is in the production and use of organic arsenicals as herbicides, insecticides, and metal preservatives.
arsenate, and arsenic trioxide are not well absorbed. Water-soluble arsenic compounds are readily absorbed via inhalation and ingestion. GI absorption of arsenic dissolved in drinking water is more than 90% (ATSDR, 2007a). At low doses, arsenic is fairly evenly distributed throughout the tissues of the body. Nails and hair, due to their high sulphydryl content, exhibit high concentrations of arsenic. After an acute high dose (i.e., fatal poisoning), arsenic is preferentially deposited in the liver and, to a lesser extent, kidney, with elevated levels also observed in the muscle, heart, spleen, pancreas, lungs, and cerebellum. Arsenic readily crosses the placenta and blood-brain barrier.

Arsenic undergoes biotransformation in humans and animals (Figure 71–9). Trivalent compounds can be oxidized back to pentavalent
Acute arsenic exposure is often associated with peripheral neuropathy involving both sensory and motor neurons. This effect is characterized by the loss of sensation in the hands and feet, often followed by muscle weakness. Neuropathy occurs several days after exposure and can be reversible following cessation of exposure, although recovery usually is not complete. Arsenic exposure may cause intellectual deficits in children (Wasserman et al., 2007).

Acute high-dose arsenic exposure causes encephalopathy in rare cases, with symptoms that can include headache, lethargy, mental confusion, hallucination, seizures, and coma.

Other Noncancer Toxicities. Acute and chronic arsenic exposures induce analgesia and leukopenia, likely via direct cytotoxic effects on blood cells and suppression of erythropoiesis. Arsenic also may inhibit heme synthesis. In the liver, arsenic causes fatty infiltrations, central necrosis, and cirrhosis of varying severity. The action of arsenic on renal capillaries, tubules, and glomeruli can cause severe kidney damage. Inhaled arsenic is irritating to the lungs, and ingested arsenic may induce bronchitis progressing to bronchopneumonia in some individuals. Chronic exposure to arsenic is associated with an increased risk of diabetes.

Carcinogenesis. Regions with very high arsenic levels in drinking water consistently have substantially higher rates of skin cancer, bladder cancer, and lung cancer. There are also associations between arsenic exposure and other cancers, including liver, kidney, and prostate tumors. Inhalation exposure to arsenic in occupational settings causes lung cancer. IARC classifies arsenic as “carcinogenic to humans (Group 1).”

The developing fetus and young children may be at increased risk of arsenic carcinogenesis because humans exposed to arsenic in utero and in early childhood have a greatly elevated risk of lung cancer (Smith et al., 2006). Studies in rodents also have observed increased cancer risks from in utero exposure and suggest that the second trimester of pregnancy represents a critical susceptibility window (Waalke et al., 2007).

Arsenic does not directly damage DNA; rather, arsenic is thought to work through changes in gene expression, DNA methylation, inhibition of DNA repair, generation of oxidative stress, or altered signal transduction pathways (Hartwig et al., 2002; Salnikow and Zhitkovich, 2008). Arsenic compounds can act as tumor promoters or cocarcinogens in rodents, particularly when combined with ultraviolet light. In humans, exposure to arsenic potentiates lung tumorigenesis from tobacco smoke. Smokers in regions with high concentrations of arsenic in the drinking water have a 5-fold increased risk of cancer over smokers living in low-arsenic regions (Ferreccio et al., 2000). Arsenic cocarcinogenesis may involve inhibition of proteins involved in nucleotide excision repair (Hartwig et al., 2002; Salnikow and Zhitkovich, 2008). Arsenic also has endocrine-disrupting activities on several nuclear steroid hormone receptors, enhancing hormone-dependent transcription at very low concentrations and inhibiting it at slightly higher levels.

Arsine Gas
Arsine gas, formed by reduction of arsenic in an industrial setting, is a rare cause of poisonings. Arsenic induces rapid and often-fatal hemolysis, which probably results from arsine combining with hemoglobin and reacting with $\text{O}_2$. A few hours after exposure, patients can develop headache, anorexia, vomiting, paresthesia, abdominal pain, chills, hemoglobinuria, bilirubinemia, and anuria. Jaundice appears after 24 h. Arsine induces renal toxicities that can progress to kidney failure. Approximately 25% of cases of arsenic exposure result in death.

Treatment
Following acute exposure to all forms of arsenic, the patient should be stabilized and further absorption of the poison should be prevented.
Close monitoring of fluid levels is important because arsenic can cause fatal hypovolemic shock. Chelation therapy is effective following short-term exposure to arsenic but has little or no benefit in chronically exposed individuals. Exchange transfusion to restore blood cells and remove arsenic is often warranted following arsenic gas exposure (Ibrahim et al., 2006).

**Cadmium**

Cadmium was discovered in 1817 and first used industrially in the mid-20th century. Cadmium is resistant to corrosion and exhibits useful electrochemical properties, which has led to its use in electroplating, galvanization, plastics, paint pigments, and nickel-cadmium batteries.

**Exposure**

In the general population, the primary source of exposure to cadmium is through food, with an estimated average daily intake of 50 μg. Cadmium also is found in tobacco and tobacco smoke; a cigarette contains 1–2 μg of cadmium (Jarup and Akeson, 2009). Workers in smelters and other metal-processing industries can be exposed to high levels of cadmium, particularly by inhalation.

**Chemistry and Mode of Action**

Cadmium exists as a divalent cation and does not undergo oxidation-reduction reactions. There are no covalent organometallic complexes of cadmium of toxicological significance. The mechanism of cadmium toxicity is not fully understood. Like lead and other divalent metals, cadmium can replace zinc in zinc-finger domains of proteins and disrupt them. Through an unknown mechanism, cadmium induces formation of ROS, resulting in lipid peroxidation and GSH depletion. Cadmium also upregulates inflammatory cytokines and may disrupt the beneficial effects of NO.

**ADME**

Cadmium is not well absorbed from the GI tract (1.5%–5%) but is absorbed via inhalation (~10%). Cadmium primarily distributes first to the liver and later the kidney, which together account for 50% of the absorbed dose. Cadmium redistributes fairly evenly to other tissues but does not cross the blood-brain barrier or the placenta. Cadmium primarily is excreted in the urine and exhibits a t\(_1/2\) of 10–30 years (ATSDR, 2012b).

**Health Effects**

**Toxicity.** Acute cadmium toxicity is due to local irritation along the absorption route. Inhaled cadmium causes respiratory tract irritation with severe, early pneumonitis accompanied by chest pains, nausea, dizziness, and diarrhea. Toxicity may progress to fatal pulmonary edema. Ingested cadmium induces nausea, vomiting, salivation, diarrhea, and abdominal cramps; the vomitus and diarrhea often are bloody.

Symptoms of chronic cadmium toxicity vary by exposure route. The lung is an important target of inhaled cadmium, while the kidney is a major target of cadmium from both inhalation and ingestion. Cadmium bound to metallothionein is transported to the kidney, where it can be released. Renal toxicity results from increased excretion of low-molecular-weight proteins, especially \(\beta_1\) microglobulin and retinol-binding protein. Cadmium also causes glomerular injury, with a resulting decrease in filtration. Chronic occupational exposure to cadmium is associated with an increased risk of renal failure and death. There is no evidence for a threshold level for cadmium’s effects on the kidney; cadmium levels consistent with normal dietary exposure can cause renal toxicity, including a reduction in glomerular filtration rate and creatinine clearance (Jarup and Akeson, 2009).

Workers with long-term inhalation exposure to cadmium exhibit decreased lung function. Symptoms include bronchitis and fibrosis of the lung, leading to emphysema. The exact cause of cadmium-induced lung toxicity is not known but may result from inhibition of the synthesis of \(\alpha_1\) antitrypsin. Chronic obstructive pulmonary disease causes increased mortality in cadmium-exposed workers.

When accompanied by vitamin D deficiency, cadmium exposure increases the risks for fractures and osteoporosis. This may be an effect of cadmium interfering with calcium and phosphate homeostasis due to its renal toxicity.

**Carcinogenicity.** Chronic occupational exposure to inhaled cadmium increases the risk of developing lung cancer (IARC, 1993; NTP, 2004). The mechanism of cadmium carcinogenesis is not fully understood. Cadmium causes chromosomal aberrations in exposed workers and treated animals and human cells. It also increases mutations and impairs DNA repair in human cells (NTP, 2004). Cadmium substitutes for zinc in DNA repair proteins and polymerases and may inhibit nucleotide excision repair, base excision repair, and the DNA polymerase responsible for repairing single-strand breaks (Hartwig et al., 2002). There is evidence that cadmium also alters cell signaling pathways and disrupts cellular controls of proliferation (Waisberg et al., 2003). Thus, cadmium acts as a nongenotoxic carcinogen.

**Treatment**

Treatment for cadmium poisoning is symptomatic. Patients who have inhaled cadmium may require respiratory support. Patients with kidney failure as a result of cadmium poisoning may require a transplant.

There is no evidence for clinical benefit from chelation therapy following cadmium poisoning, and chelation therapy may result in adverse effects (ATSDR, 2012b).

**Chromium**

Chromium is an industrially important metal used in a number of alloys, particularly stainless steel, which contains at least 11% chromium. Chromium can be oxidized to multiple valence states, with trivalent (Cr\(^{III}\)) and hexavalent (Cr\(^{VI}\)) being the two forms of biological importance. Chromium exists almost exclusively as the trivalent form in nature, and Cr\(^{III}\) is an essential metal involved in the regulation of glucose metabolism. Cr\(^{VI}\) is thought to be responsible for the toxic effects of chromium (ATSDR, 2012a).

**Exposure**

Exposure to chromium in the general population primarily is through the ingestion of food, although there also is exposure from drinking water and air. Workers are exposed to chromium during chrome production, stainless steel production and welding, chromium plating, ferrochrome alloy and chrome pigment production, and in tanning industries. Exposure usually is to a mixture of Cr\(^{III}\) and Cr\(^{VI}\).

**Chemistry and Mode of Action**

Chromium occurs in its metallic state or in any valence state between divalent and hexavalent. Cr\(^{III}\) is the most stable and common form. Cr\(^{VI}\) is corrosive and is readily reduced to lower valence states. The primary reason for the different toxicological properties of Cr\(^{II}\) and Cr\(^{VI}\) is thought to be differences in their absorption and distribution. Hexavalent chromium resembles sulfate and phosphate and can be taken across membranes by anion transporters. Once inside the cell, Cr\(^{III}\) undergoes a series of reduction steps, ultimately forming Cr\(^{III}\), which is thought to cause most of the toxic effects. Trivalent chromium readily forms covalent interactions with DNA. Hexavalent chromium also induces oxidative stress and hypersensitivity reactions.

**ADME**

Absorption of inhaled chromium depends on its solubility, valence state, and particle size. Smaller particles are deposited deeper in the lungs. Absorption into the bloodstream of hexavalent and soluble forms is higher than the trivalent or insoluble forms, with the remainder often retained in the lungs. Approximately 50%–85% of inhaled Cr\(^{III}\) particles (<5 μm) are absorbed. Absorption of ingested chromium is less than 10% and varies depending on water solubility. Cr\(^{III}\) crosses membranes by facilitated transport, while Cr\(^{VI}\) crosses by diffusion. Cr\(^{II}\) is distributed to all of the tissues and crosses the placenta. The highest levels are attained in the liver, kidney, and bone; Cr\(^{III}\) also is retained in erythrocytes. Excretion primarily is through urine, with small amounts also excreted in bile and breast milk and deposited in hair and nails. The \(t_{1/2}\) of ingested Cr\(^{III}\) is about 40 h; the \(t_{1/2}\) of Cr\(^{VI}\) is about 10 h (ATSDR, 2012a).

**Health Effects**

**Toxicity.** Acute exposure to very high doses of chromium causes death via damage to multiple organs, particularly the kidney. Chronic low-dose
chromium exposure causes toxicity at the site of contact. Workers exposed to inhaled chromium develop symptoms of lung and upper respiratory tract irritation, decreased pulmonary function, and pneumonia. Chronic exposure to chromium via ingestion, including after mucociliary clearance of inhaled particles, causes symptoms of GI irritation (oral ulcer, diarrhea, abdominal pain, indigestion, and vomiting). Cr⁶⁺ is a dermal irritant and can cause ulceration or burns. Low-dose exposure by any route causes some individuals to become sensitized. These individuals will develop allergic dermatitis following dermal exposure to chromium, including products containing metallic chromium. Chromium-sensitized workers often also develop asthma following inhalation exposure (ATSDR, 2012a).

Carcinogenicity. The Cr⁶⁺ compounds are group 1 human carcinogens (IARC, 1990). There is insufficient evidence for carcinogenicity from metallic and trivalent chromium (classified in IARC group 3). Workers exposed to Cr⁶⁺ via inhalation have elevated incidence of and mortality from lung and nasal cancer. Environmental exposure to Cr⁶⁺ in drinking water increases the risk of developing stomach cancer.

There are multiple potential mechanisms for chromium carcinogenicity (Salnikow and Zhitkovich, 2008). Reduction of Cr⁶⁺ to Cr⁴⁺ occurs with concomitant oxidation of cellular molecules. Ascorbate is the primary reductant, but other molecules, including GSH, lipids, proteins, and DNA, also can be oxidized. Cr⁴⁺ forms a large number of covalent DNA adducts, primarily at the phosphate diester backbone. The DNA adducts are not very mutagenic and are repaired by nucleotide excision repair. It is thought that the high level of nucleotide excision repair activity following chromium exposure contributes to carcinogenesis, either by preventing repair of mutagenic lesions formed by other carcinogens or through the formation of single-strand breaks due to incomplete repair. Chromium also forms cross-links between DNA and protein. Chronic inflammation due to chromium-induced irritation also may promote tumor formation.

Treatment

There are no standard protocols for treatment for acute chromium poisoning. One approach that has shown promise in rodents is the use of reductants such as ascorbate, GSH, or N-acetylcysteine to reduce Cr⁶⁺ to Cr⁴⁺ after exposure but before absorption to limit bioavailability (ATSDR, 2012a). These compounds and EDTA also increase urinary excretion of chromium after high-dose exposure, particularly if given soon enough to prevent uptake into cells. Exchange transfusion to remove chromium from plasma and erythrocytes may be beneficial.

Treatment for Metal Exposure

The most important response to environmental or occupational exposures to metals is to eliminate the source of the exposure. It also is important to stabilize the patient and provide symptomatic treatment.

Treatment for acute metal intoxications often involves the use of chelators. A chelator is a compound that forms stable complexes with metals, typically as five- or six-membered rings. Formation of complexes between chelators and metals should prevent or reverse metal binding to biological ligands. The ideal chelator should be highly soluble in water, be resistant to biotransformation, reach sites of metal storage, form stable and nontoxic complexes with toxic metals, and be readily excreted as a metal-chelator complex. A low affinity for the essential metals calcium and zinc also is desirable because toxic metals often compete with these metals for protein binding.

In cases of acute exposure to high doses of most metals, chelation therapy reduces toxicity. However, following chronic exposure, chelation therapy does not show clinical benefits beyond those of cessation of exposure alone and, in some cases, does more harm than good. Chelation therapy may increase the neurotoxic effects of heavy metals and is only recommended for acute poisonings. The structures of the most commonly used chelators are shown in Figure 71–10.

Ethymenediaminetetraacetic Acid

EDTA and its various salts are effective chelators of divalent and trivalent metals. CaNa₂EDTA is the preferred EDTA salt for metal poisoning, provided that the metal has a higher affinity for EDTA than calcium. CaNa₂EDTA is effective for the treatment for acute lead poisoning, particularly in combination with dimercaprol, but is not an effective chelator of mercury or arsenic in vivo.

Chemistry and Mode of Action

The pharmacological effects of CaNa₂EDTA result from chelation of divalent and trivalent metals in the body. Accessible metal ions with a higher affinity for CaNa₂EDTA than Ca⁺ will be chelated, mobilized, and usually excreted. Because EDTA is charged at physiological pH, it does not significantly penetrate cells. CaNa₂EDTA mobilizes several endogenous metallic cations, including zinc, manganese, and iron. Additional supplementation with zinc following chelation therapy may be beneficial. The most common therapeutic use of CaNa₂EDTA is for acute lead intoxication. CaNa₂EDTA does not provide clinical benefits for the treatment for chronic lead poisoning.

CaNa₂EDTA is available as edetate calcium disodium (Calcium Disodium Versenate). Intramuscular administration of CaNa₂EDTA results in good absorption, but pain occurs at the injection site; consequently, the chelator injection often is mixed with a local anesthetic or administered intravenously. For intravenous use, CaNa₂EDTA is diluted in either 5% dextrose or 0.9% saline and is administered slowly by intravenous drip. A dilute solution is necessary to avoid thrombophlebitis.

ADME

Less than 5% of CaNa₂EDTA is absorbed from the GI tract. After intravenous administration, CaNa₂EDTA has a t₁/₂ of 20–60 min. In blood, CaNa₂EDTA is found only in the plasma. CaNa₂EDTA is excreted in the urine by glomerular filtration, so adequate renal function is necessary for successful therapy. Altering either the pH or the rate of urine flow has no effect on the rate of excretion. There is very little metabolic degradation of EDTA. The drug is distributed mainly in the extracellular fluids; little gains access to the spinal fluid (5% of the plasma concentration).

Toxicity

The principal toxic effect of CaNa₂EDTA is on the kidney. Repeated large doses of the drug can eventually cause degeneration of proximal tubular cells. The early renal effects usually are reversible, and urinary abnormalities disappear rapidly with cessation of treatment. The most likely mechanism of toxicity is chelation of essential metals, particularly zinc, in proximal tubular cells. To minimize nephrotoxicity, adequate urine...
production should be established prior to and during treatment with CaNa₂EDTA. For patients with lead encephalopathy and cerebral edema, CaNa₂EDTA can lead to a potentially fatal increase in intracranial pressure following intravenous administration. Intramuscular administration is preferred for these patients.

Rapid intravenous administration of a form lacking calcium, such as Na₂EDTA, causes hypocalcemic tetany. However, a slow infusion (<15 mg/min) administered to a normal individual elicits no symptoms of hypocalcemia because of the availability of extracellular stores of Ca²⁺. In contrast, CaNa₂EDTA can be administered intravenously with no untoward effects because the change in the concentration of Ca²⁺ in the plasma and total body is negligible.

Other side effects associated with CaNa₂EDTA include malaise, fatigue, and excessive thirst, followed by the sudden appearance of chills and fever and subsequent myalgia, frontal headache, anorexia, occasional nausea and vomiting, and rarely, increased urinary frequency and urgency. CaNa₂EDTA is teratogenic in laboratory animals, probably as a result of zinc depletion; it should be used in pregnant women only under conditions in which the benefits clearly outweigh the risks (Kalina and Flora, 2005). Other possible effects include sneezing, nasal congestion, and lacrimation; glycosuria; anemia; dermatitis with lesions strikingly similar to those of vitamin B₁₂ deficiency; transitory lowering of systolic and diastolic blood pressures; prolonged prothrombin time; and T-wave inversion on the electrocardiogram.

**Dimercaprol**

Dimercaprol was developed during World War II as an antidote to lewisite, a vesicant arsenical war gas, hence its alternative name, British anti-Lewisite (BAL). Arsenicals and other heavy metals form a stable and relatively nontoxic chelate ring with dimercaprol.

**Chemistry and Mode of Action**

The pharmacological actions of dimercaprol result from formation of chelation complexes between its sulfhydryl groups and metals. Dissociation of dimercaprol-metal complexes and oxidation of dimercaprol occur in vivo. The sulfur-metal bond may be labile in the acidic tubular urine, which may increase the delivery of metal to renal tissue and increase toxicity. The dosage regimen should maintain a concentration of dimercaprol in plasma adequate to favor the continuous formation of the more stable 2:1 (BAL-metal) complex. However, because of pronounced and dose-related side effects, excessive plasma concentrations must be avoided. The concentration in plasma therefore must be maintained by repeated dosage until the metal is excreted. Dimercaprol is most beneficial when given very soon after exposure to the metal because it is more effective in preventing inhibition of sulfhydryl enzymes than in reactivating them. Dimercaprol limits toxicity from arsenic, gold, and mercury, which form mercaptides with essential cellular sulfhydryl groups. It also is used in combination with CaNa₂EDTA to treat lead poisoning. Dimercaprol should not be used in iron, cadmium, or selenium poisoning because the resulting metal complexes are more toxic than the metal alone, especially to the kidneys.

**ADME**

Dimercaprol is given by deep intramuscular injection as a 100-mg/mL solution in peanut oil and should not be used in patients who are allergic to peanuts. Peak dimercaprol concentrations in blood are attained in 30–60 min. The t₁/₂ is short, and metabolic degradation and excretion essentially are complete within 4 h. Dimercaprol and its chelates are excreted in both urine and bile. Dimercaprol is contraindicated for use following chronic exposures to heavy metals because it does not prevent neurotoxic effects. There is evidence in laboratory animals that dimercaprol mobilizes lead and mercury from various tissues to the brain (Andersen and Aaseth, 2002). This effect may be due to the lipophilic nature of dimercaprol and is not observed with its more hydrophilic analogues described further in the chapter (see Succimer and Sodium 2,3-Dimercaptopropane-1-sulfonate).

**Toxicity**

Side effects occur in about 50% of subjects receiving 5 mg/kg intramuscularly. Dimercaprol causes a rise in systolic and diastolic arterial pressures, accompanied by tachycardia. The pressure rises immediately but returns to normal within 2 h. Dimercaprol also can cause anxiety and unrest, nausea and vomiting, headache, a burning sensation in the mouth and throat, a feeling of constriction or pain in the throat and chest, conjunctivitis, blepharospasm, lacrimation, rhinorrhea, salivation, tingling of the hands, a burning sensation in the penis, sweating, abdominal pain, and the occasional appearance of painful sterile abscesses at the injection site. The dimercaprol-metal complex breaks down easily in an acidic medium; production of alkaline urine protects the kidney during therapy. Children react similarly to adults, although about 30% also may experience a fever that disappears on drug withdrawal. Dimercaprol is contraindicated in patients with hepatic insufficiency, except when this condition is a result of arsenic poisoning.

**Succimer**

Succimer (2,3-dimercaptosuccinic acid [DMSA]) has been approved in the U.S. for treatment of children with BLL greater than 45 μg/dL. Because of its oral availability, improved toxicity profile, and selective chelation of heavy metals, succimer also is used off label for the treatment of adults with lead poisoning and for the treatment for arsenic and mercury intoxication, although no large clinical trials have been undertaken for these indications.

**Chemistry and Mode of Action**

Succimer is an orally effective chelator that is chemically similar to dimercaprol but contains two carboxylic acids that modify the spectrum of absorption, distribution, and chelation of the drug. It has an improved toxicity profile over dimercaprol.

**ADME**

After absorption, succimer is biotransformed to a mixed disulfide with cysteine (Aposhian and Aposhian, 2006). Succimer lowers BLL and attenuates lead toxicity. The succimer-lead chelate is eliminated in both urine and bile. The fraction eliminated in bile can undergo enterohepatic circulation.

Succimer has several desirable features over other chelators. It is orally bioavailable, and because of its hydrophilic nature, it does not mobilize metals to the brain or enter cells. It also does not significantly chelate essential metals such as zinc, copper, or iron. As a result of these properties, succimer exhibits a much better toxicity profile relative to other chelators. Animal studies suggest that succimer also is effective as a chelator of arsenic, cadmium, mercury, and other toxic metals (Andersen and Aaseth, 2002; Kalina and Flora, 2005).

**Toxicity**

Succimer is much less toxic than dimercaprol. The most commonly reported adverse effects are nausea, vomiting, diarrhea, and loss of appetite. In a few patients, rashes necessitate discontinuation of therapy. Transient elevations in hepatic transaminases have been observed with succimer treatment.

**Sodium 2,3-Dimercaptopropane-1-sulfonate**

Another dimercapto compound, DMPS, is used for the chelation of heavy metals. DMPS is not approved by the FDA but is approved for use in Germany. DMPS is available from compounding pharmacies and is used by some doctors in the U.S.

**Chemistry and Mode of Action**

DMPS is a clinically effective chelator of lead, arsenic, and especially mercury. It is orally available and is rapidly excreted, primarily through the kidneys. It is negatively charged and exhibits distribution properties similar to those of succimer. DMPS is less toxic than dimercaprol but mobilizes zinc and copper and thus is more toxic than succimer. In a small clinical trial, DMPS exhibited some clinical benefit for the treatment for chronic arsenic poisoning (Kalina and Flora, 2005), but more thorough clinical studies are needed.

**Penicillamine; Trientine**

Penicillamine is an effective chelator of copper, mercury, zinc, and lead and promotes the excretion of these metals in the urine. Penicillamine
is indicated for use in patients with Wilson disease (excess body burden of copper due to diminished excretion) and is used in other heavy metal intoxications. Penicillamine is more toxic and is less potent and selective for chelation of heavy metals relative to other available chelation drugs. It is therefore not a first-line treatment for acute intoxication with lead, mercury, or arsenic. However, because it is inexpensive and orally bioavailable, it often is given at fairly low doses following treatment with CaNa₂EDTA or dimercaprol to ensure that the concentration of metal in the blood stays low following the patient’s release from the hospital.

**ADME**

Penicillamine is well absorbed (40%–70%) from the GI tract. Food, antacids, and iron reduce its absorption. Peak concentrations in blood are obtained 1–3 h after administration. Penicillamine is relatively stable in vivo compared to its unmethylated parent compound cysteine. Hepatic biotransformation is important for degradation of penicillamine; very little drug is excreted unchanged. Metabolites are found in both urine and feces. N-Acetylpenicillamine is more effective than penicillamine in protecting against the toxic effects of mercury, presumably because it is more resistant to metabolism.

**Therapeutic Use**

Penicillamine is available for oral administration. For chelation therapy, the usual adult dose is 1–1.5 g/d in four divided doses, given on an empty stomach to avoid interference by metals in food. Penicillamine is used in Wilson disease, cystinuria, and rheumatoid arthritis (rarely). For the treatment for Wilson’s disease, 1–2 g/d usually is administered in four divided doses. The urinary excretion of copper should be monitored to determine whether the dosage of penicillamine is adequate.

**Toxicity**

Penicillamine induces cutaneous lesions, including urticaria, macular or papular reactions, pemphigoid lesions, lupus erythematosus, and dermatomyositis. It also causes dryness and scaling. Cross-reactivity with penicillin may be responsible for some episodes of urticarial or maculopapular reactions with generalized edema, pruritus, and fever that occur in as many as one-third of patients taking penicillamine. Hematological reactions may be fatal and include leukopenia, aplastic anemia, and agranulocytosis. Renal toxicity induced by penicillamine usually is manifested as reversible proteinuria and hematuria, but it may progress to nephrotic syndrome with membranous glomerulopathy. Rare fatalities have been reported from Goodpasture syndrome. Severe dyspnea, although uncommon, has been reported from penicillamine-induced bronchial asthma. Myasthenia gravis also has been induced by long-term therapy with penicillamine. A specific schedule for physical and laboratory monitoring for skin, blood, kidney, lung, liver, and other toxicities is published in the manufacturer’s product labeling.

Penicillamine is a teratogen in laboratory animals, but for pregnant women with Wilson disease, the benefits outweigh the risks. Less serious side effects include nausea, vomiting, diarrhea, dyspepsia, anorexia, and a transient loss of taste for sweet and salt, which is relieved by supplementation of the diet with copper. Contraindications to penicillamine therapy include pregnancy in the absence of Wilson disease, renal insufficiency, or a previous history of penicillamine-induced agranulocytosis or aplastic anemia. Penicillamine increases the requirement for pyridoxine; supplementation with 25 mg daily is advised.

**Trientine**

Trientine (trihydmethyltetramine dihydrochloride) is an acceptable alternative for patients with Wilson disease who are intolerant of penicillamine. Trientine is effective orally. Maximal daily doses of 2 g for adults or 1.5 g for children are taken in two to four divided portions on an empty stomach. Iron deficiency may occur during trientine therapy; this can be overcome with short courses of iron therapy, but iron and trientine should not be ingested within 2 h of each other.

---

**Deferoxamine; Deferasirox; Deferiprone**

**Chemistry and Mode of Action**

Deferoxamine is isolated as the iron chelate from *Streptomyces pilosus* and is treated chemically to obtain the metal-free ligand. Deferoxamine (defereroxamine mesylate, Desferal) has a remarkably high affinity for ferric iron ($K_a = 10^{34}$ M⁻¹) coupled with a very low affinity for calcium ($K_a = 10^{3.5}$). In vitro, it removes iron from hemosiderin and ferritin and, to a lesser extent, from transferrin. Iron in hemoglobin or cytochromes is not removed by deferoxamine.

**ADME and Therapeutic Use**

Deferoxamine is poorly absorbed after oral administration, and parenteral (intravenous, intramuscular, or subcutaneous) administration is required. For acute iron toxicity, intramuscular administration is preferred, except for patients in cardiovascular collapse or shock. For patients in shock, the drug is administered intravenously at 10–15 mg/kg/h by constant infusion for the first 1000 mg. If additional treatment is needed beyond 1000 mg, it should be administered at a rate not to exceed 125 mg/h. Faster rates of infusion usually are associated with hypotension. For acute iron poisoning without cardiovascular collapse or shock, deferoxamine should be given intramuscularly at a dose of 50 mg/kg with a maximum dose of 1 g. Subsequent doses of 500 mg may be given, if needed, every 4–12 h. Hypotension also can occur with the intramuscular route. For chronic iron intoxication (e.g., thalassemia), subcutaneous administration is recommended. Continuous subcutaneous administration should be given to achieve a dose of 1–2 g/d. The duration of the infusion (8–24 h) should be individualized to the patient. Poorly compliant patients with thalassemia can be given deferoxamine by slow intravenous infusion (rate not to exceed 15 mg/kg/h) prior to or after receiving transfusion. Deferoxamine may also be administered via an intramuscular dose of 0.5–1.0 g/d. Deferoxamine is not recommended in primary hemochromatosis; phlebotomy is the treatment of choice. Off label, deferoxamine has also been used for the chelation of aluminum in dialysis patients.

Deferoxamine is metabolized to unknown products by plasma enzymes. The parent drug and its metabolites are readily excreted in the urine.

**Toxicity**

Deferoxamine can cause a number of allergic reactions, including pruritus, wheals, rash, and anaphylaxis. Other adverse effects include dysuria, abdominal discomfort, diarrhea, fever, leg cramps, and tachycardia. Occasional cases of cataract formation have been reported. Deferoxamine may cause neurotoxicity during long-term, high-dose therapy for transfusion-dependent thalassemia major; both visual and auditory changes have been described. A “pulmonary syndrome” has been associated with high-dose (10–25 mg/kg/h) deferoxamine therapy; tachypnea, hypoxemia, fever, and eosinophilia are prominent symptoms. Contraindications to the use of deferoxamine include renal insufficiency and anuria; during pregnancy, the drug should be used only if clearly indicated.

**Deferasirox; Deferiprone**

Deferasirox and deferiprone are oral chelators that are FDA approved to treat chronic iron overload in patients receiving transfusions. Deferasirox is also indicated for the treatment for chronic iron overload in nontransfusion-dependent thalassemia syndromes. Because of their oral availability, these drugs may allow for better compliance rates for patients with thalassemia. Both drugs form an uncharged chelate with iron and appear to be more effective than deferoxamine at reducing cardiac iron. However, both carry black-box warnings (deferaxirox for renal failure, hepatic failure, GI hemorrhage; deferiprone for agranulocytosis, neutropenia), and there are currently insufficient data to recommend replacing deferoxamine as the first-line treatment for chronic iron overload.

**Acknowledgment:** Curtis D. Klaassen contributed to this chapter in earlier editions of this book. We have retained some of his text in the current edition.

Principles of Prescription Order Writing and Patient Compliance
Iain L.O. Buxton

Latin Not Spoken Here

In writing prescriptions, use English (in the U.S.) or the dominant language of the patient. Latin is no longer the international language of medicine, but a number of commonly used abbreviations derive from obsolete Latin usage and persist in prescription writing. Avoid using them. Non utuntur Latini.

Some Latin seems firmly embedded in pharmacy practice. “Rx” is said to be an abbreviation for the Latin word recipere, meaning “take” or “take thus,” as a direction to a pharmacist, preceding the physician’s “recipe” for preparing a medication. The abbreviation “Sig” for the Latin Signatura, is used on the prescription to mark the directions for administration of the medication.

Who Can Prescribe Medicines?

Prescription writing in the U.S. is regulated by state boards of pharmacy. In many states, healthcare practitioners other than MD and DO physicians can write prescriptions, although in some cases narcotics are excluded. Licensed dentists, podiatrists, PAs, nurse practitioners, pharmacists, and clinical psychologists can prescribe medications under various circumstances.

Current Practice

The prescription consists of the superscription, the inscription, the subscription, and the name and signature of the prescriber, all contained on a single form (Figure AI–1). The superscription includes the date the prescription order is written; the name, address, weight, and age of the patient; and the Rx (Take). The body of the prescription, or inscription, contains the name and amount or strength of the drug to be dispensed or the name and strength of each ingredient to be compounded.

The subscription is the instruction to the pharmacist, usually consisting of a short sentence, such as “dispense 30 tablets.” The siga or “Sig” is the instruction for the patient regarding how to take the prescription, interpreted and transposed onto the prescription label by the pharmacist. In the U.S., prescriptions should always be written in English. Many physicians continue to use Latin abbreviations, such as, “1 cap tid pc.” This will be interpreted by the pharmacist as “take one capsule three times daily after meals.” However, the use of Latin abbreviations for these directions only mystifies the prescription and is discouraged. The pharmacist should always write the label in English (or, as appropriate, in the language of the patient). The use of such abbreviations or symbols is a confounding practice; many serious dispensing errors can be traced to the use of abbreviations.

Avoid the instruction “take as directed.” Such directions assume an understanding on the part of the patient that may not be realized and are inadequate for the pharmacist, who must determine the intent of the physician before dispensing the medication. Including directions provides an additional measure of safety for the patient because the pharmacist can confirm the correct medication is being dispensed for the prescribed regimen. The best directions to the patient will include a reminder of the intended purpose of the medication by including such phrases as “for relief of pain” or “to relieve itching.” The correct route of administration is reinforced by the choice of the first word of the directions. For an oral dosage form, the directions should begin with take or give; for externally applied products, the word apply; for suppositories, insert; and for eye, ear, or nose drops, place, preferable to “instill.”

Include Patient Information and Dosage Calculations

The patient’s name and address are needed on the prescription order to ensure that the correct medication goes to the proper patient and also for identification and recordkeeping. For medications whose dosage involves a calculation, a patient’s pertinent factors, such as weight, age, or body surface area, also should be listed on the prescription; both the calculated dose and the dosage formula used, such as “240 mg every 8 h (40 mg/kg/d),” should be included to allow another healthcare professional to double check the prescribed dosage. Pharmacists always should recalculate dosage equations when filling such prescriptions. Medication orders in hospitals and some clinic settings, such as those for antibiotics or anti-seizure medications that are sometimes difficult to adequately dose (e.g., phenytoin), can specify the patient diagnosis and desired drug and request dosing by the clinical pharmacist. This is commonly done for drugs with significant adverse effect potential, such as vancomycin.

Proper Use of Prescription Pad

Prescription pad blanks are normally imprinted with a heading that gives the name of the physician and the address and phone number of the practice site (Figure AI–1). When using institutional blanks that do not bear

USAN: U.S. Adopted Name
USP: U.S. Pharmacopeia
USP MERP: U.S. Pharmacopeia Medication Errors Reporting Program
USP/NF: USP/National Formulary

Figure AI–1  The prescription. The prescription must be accurately and legibly prepared to identify the patient, the medication to be dispensed, and the mode of drug administration. Avoid abbreviations and Latin; they lead to dispensing errors. Include the therapeutic purpose in the subscription (e.g., “for control of blood pressure”) to prevent errors in dispensing. For example, the use of losartan for the treatment of hypertension may require 100 mg/d (1.4 mg/kg/d), whereas for treatment of congestive heart failure, the dose of this angiotensin II receptor antagonist generally should not exceed 50 mg/d. Including the therapeutic purpose of the prescription also can assist patients in organizing and understanding their medications. Including the patient’s weight on the prescription can be useful in avoiding dosing errors, particularly when drugs are administered to children.
Immediate administration is necessary.

Physicians come under the jurisdiction of the CSA are divided into five schedules for the enforcement of the federal CSA. The DEA regulates each step of the handling of controlled substances from manufacture to dispensing.

In the U.S., the DEA within the Department of Justice is responsible for the enforcement of the federal CSA. The DEA regulates each step of the handling of controlled substances from manufacture to dispensing (21 U.S.C. § 811). The law provides a system that is intended to prevent diversion of controlled substances from legitimate uses. Substances that come under the jurisdiction of the CSA are divided into five schedules (Box AI–1); individual states may have additional schedules. Physicians must be authorized to prescribe controlled substances by the board of pharmacy in the jurisdiction in which they are licensed, and they must be registered with the DEA or exempted from registration as defined under the CSA. The number on the certificate of registration must be indicated on all prescription orders for controlled substances. Criminal prosecution and penalties for misuse generally depend on the schedule of a substance and the amount of drug in question.

### Prescribing Controlled Substances

To be valid, a prescription for a controlled substance must be issued for a legitimate medical purpose by an individual practitioner acting in the usual course of his or her professional practice. An order that does not meet these criteria is not considered a legitimate prescription within the meaning of the law and thus does not protect either the physician who issues it or the pharmacist who dispenses it. Most states prohibit physicians from prescribing controlled substances for themselves. It is prudent to follow this guideline even if compliance is not mandated by law.

Specific requirements, both state and federal, apply to prescriptions for schedule II drugs. For example, all such prescriptions must be written in ink, and refills of schedule II drugs are not allowed. Whether intended for schedule II or lesser scheduled medications, prescriptions for controlled substances must, by law, include the patient’s full name and address and the practitioner’s full name, address, and DEA registration number. The prescription must also include the drug name, strength, quantity, directions for use, and the number of refills, if allowed (based on the category of the drug). The CSA requires that all orders for controlled substances be dated as of, and signed on, the day issued and prohibits filling or refilling orders for substances in schedules III and IV beyond more than 6 months after their date of issuance. State agencies may impose additional regulations, such as requiring that prescriptions for controlled substances be printed on triplicate or state-issued prescription pads or restricting the use of a particular class of drugs for specific indications. All medical personnel should be familiar with the latest CDC recommendations for prescribing opioids for chronic pain (Table 20–7).

### Oral Orders

Prescriptions for schedule III, IV, and V medications may be telephoned to a pharmacy by a physician in the same manner as a prescription for a noncontrolled substance, although it is in the physician’s best interest to keep his or her DEA number as private as possible (see Preventing Diver
tion). Schedule II prescriptions may be telephoned to a pharmacy only in emergency situations, that is:

- Immediate administration is necessary.
- No appropriate alternative treatment is available.
- It is not reasonably possible for the physician to provide a written prescription prior to the dispensing.

For an emergency prescription, the quantity must be limited to the amount adequate to treat the patient during the emergency period, and the physician must have a written prescription delivered to the pharmacy for that emergency within 72 h. If mailed, the prescription must be postmarked within 72 h. The pharmacist must notify the DEA if this prescription is not received.

### Refills

No prescription order for a schedule II drug may be refilled under any circumstance (CFR Title 21 §1306). Pre-dated original prescriptions may be used when therapy beyond the period covered by the first prescription is needed, but these are generally discouraged. For schedule III and IV drugs, refills may be issued either orally or in writing, not to exceed five refills or 6 months after the issue date, whichever comes first. Beyond this time, a new prescription must be ordered. For schedule V drugs, there are no restrictions on the number of refills allowed, but if no refills are noted at the time of issuance, a new prescription must be made for additional drug to be dispensed.

### Preventing Diver
tion

Prescription blanks often are stolen and used to sustain abuse of controlled substances. To prevent this type of diversion, prescription pads should be

---

**Box AI–1 Controlled Substance Schedules**

**Schedule I** (examples: heroin, methylene dioxymethylamphetamine, lysergic acid diethylamide, mescaline, and all salts and isomers thereof):

1. High potential for abuse.
2. No accepted medical use in the U.S. or lacks accepted safety for use in treatment in the U.S. May be used for research purposes by properly registered individuals.

**Schedule II** (examples: morphine, oxycodone, fentanyl, meperidine, dextroamphetamine, cocaine, amobarbital):

1. High potential for abuse.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to severe psychological or physical dependence.

**Schedule III** (examples: anabolic steroids, nalorphine, ketamine, certain schedule II substances in suppositories, mixtures, or limited amounts per dosage unit):

1. Abuse potential less than substances in schedule I or schedule II.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to moderate-to-low physical dependence or high psychological dependence.

**Schedule IV** (examples: alprazolam, phenobarbital, meprobamate, modafinil):

1. Abuse potential less than substances in schedule III.
2. Has a currently accepted medical use in the U.S.
3. Abuse of substance may lead to limited physical or psychological dependence relative to substances in schedule III.

**Schedule V** (examples: buprenorphine, products containing a low dose of an opioid plus a nonnarcotic ingredient such as cough syrup with codeine and guaifenesin, antidiarrheal tablets with diphenoxylate and atropine):

1. Low potential for abuse relative to schedule IV.
2. Has a currently accepted medical use in the U.S.
3. Some schedule V products may be sold in limited amounts without a prescription at the discretion of the pharmacist; however, if a physician wishes a patient to receive one of these products, it is preferable to provide a prescription.

---

*Although codeine is a schedule II drug, its dosage in cough syrups is regarded as sufficiently low to permit their classification as schedule V substances.*

---

that will influence their prescribing habits; use of the original medical literature and online resources such as the Cochrane evidentiary reviews (http://www.cochrane.org) will ensure instruction of the prescriber’s best judgment. The amount of a drug to be dispensed should be clearly stated and should be only that needed by the patient. Excessive amounts should never be dispensed because this not only is expensive for the patient but also may lead to accumulation of medicines, which can lead to harm to the patient or members of the patient’s family if used inappropriately. Better to require several refills of a prescription than to prescribe and dispense more than necessary at one time.

---

**Controlled Substances**

In the U.S., the DEA within the Department of Justice is responsible for the enforcement of the federal CSA. The DEA regulates each step of the handling of controlled substances from manufacture to dispensing (21 U.S.C. § 811). The law provides a system that is intended to prevent diversion of controlled substances from legitimate uses. Substances that come under the jurisdiction of the CSA are divided into five schedules (Box AI–1); individual states may have additional schedules. Physicians must be authorized to prescribe controlled substances by the board of pharmacy in the jurisdiction in which they are licensed, and they must be
Pregnancy Category C: This compendium is recognized by control schedule. Drug schedules in the U.S. are listed in Box AI–1 and described in the USP/NF , the official drug standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP/NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such standards are essential for agents possessing biological activity, such as insulin or antibody-based medications.

Drug Standards and Classification

The U.S. Pharmacopeial Convention, Incorporated, is a non-governmental organization that disseminates authoritative standards and information on medicines and other healthcare technologies. This organization is home to the USP, which, together with the FDA, the pharmaceutical industry, and health professions, establishes authoritative drug standards. These standards are enforceable by the FDA and governments of other countries and are recognized worldwide. Drug monographs are published in the USP/NF, the official drug standards compendia that organize drugs into categories based on pharmacological actions and therapeutic uses. The USP also provides chemical reference standards to carry out the tests specified in the USP/NF. For example, a drug to be manufactured and labeled in units must comply with the USP standard for units of that compound. Such standards are essential for agents possessing biological activity, such as insulin or antibody-based medications.

The USP also is home to the USP Dictionary of U.S. Adopted Names (USAN) and International Drug Names. This compendium is recognized throughout the healthcare industry as the authoritative dictionary of drugs. Entries include one or more of the following: U.S. Adopted Names, official drug names for the NF, previously used official names, International Nonproprietary Names, British Approved Names, Japanese Accepted Names, trade names, and other synonyms. In addition to names, the records in this file contain other substance information, such as CAS, RN, molecular formula, molecular weight, pharmacological or therapeutic category, drug sponsor, reference information, and structure diagram, if available. The USP maintains an electronic website that can be accessed for useful information on drug naming, classification, and standards (http://www.usp.org).

In the U.S., drug products also are coded under the NDC. The NDC serves as a universal product identifier for drugs used in humans. The current edition of the NDC Directory is limited to prescription drugs and a few selected over-the-counter products. Each drug product listed under the Federal Food, Drug, and Cosmetic Act is assigned a unique 10-digit, 3-segment number. This number, the NDC number, identifies the labeler/vendor, product, and package size. The labeler/vendor code is assigned by the FDA. The second segment, the product code, identifies a specific strength, dosage form, and formulation for a particular drug company. The third segment, the package code, identifies package sizes. Both the product and package codes are assigned by the manufacturer. In addition to classification of drugs by therapeutic category, drugs also are grouped by control schedule. Drug schedules in the U.S. are listed in Box AI–1 and discussed under Controlled Substances.

The FDA also categorizes drugs that may be used in pregnant women. These categories are similar to those used in other countries and provide guidance based on available science. The categories range from A to X, in increasing order of concern:

- **Pregnancy Category A**: Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters). Because of the obvious nature of the risk associated with the use of medications during gestation, the FDA requires a body of high-quality data on a drug before it can be considered for Pregnancy Category A. Drugs in this category include levotyphrine and folic acid.

- **Pregnancy Category B**: Animal reproduction studies have failed to demonstrate a risk to the fetus, and there are no adequate and well-controlled studies in pregnant women. OR animal studies have shown an adverse effect, but adequate and well-controlled studies in pregnant women have failed to demonstrate a risk to the fetus in any trimester. Drugs in this category include metformin and hydrochlorothiazide and should be prescribed only as needed for maternal health.

- **Pregnancy Category C**: Animal reproduction studies have shown an adverse effect on the fetus, and there are no adequate and well-controlled studies...
Compliance

Compliance is the extent to which the patient follows a regimen prescribed by a healthcare professional. The patient is the final and most important determinant of how successful a therapeutic regimen will be and should be engaged as an active participant who has a vested interest in its success. Whatever term is used—compliance, adherence, therapeutic alliance, or concordance—physicians must promote a collaborative interaction between doctor and patient in which each brings an expertise that helps to determine the course of therapy. The patient’s quality-of-life beliefs may differ from the clinician’s therapeutic goals, and the patient will have the last word every time when there is an unresolved conflict.

Hundreds of variables that may influence compliance behavior have been identified. A few of the most frequently cited are in Box AI–2, along with some suggestions for improving compliance, although none guarantees 100% compliance.

Noncompliance may be manifest in drug therapy as intentional or accidental errors in dosage or schedule, overuse, underuse, early termination of therapy, or not having a prescription filled; therapeutic failures can result (Malek and Grosset, 2015). Noncompliance always should be considered in evaluating potential causes of inconsistent or nonexistent response to therapy. The reported incidence of patient noncompliance usually is in the range of 30%–60%; the rate for long-term regimens is about 50% and can be improved by medication management (Klein et al., 2009).

The Patient-Provider Relationship

Patient satisfaction with the physician has a significant impact on compliance behavior. Patients are more likely to follow instructions and recommendations when their expectations for the patient-provider relationship and for their treatment are met. These expectations include not only clinical but also interpersonal competence; thus, cultivating good interpersonal and communication skills is essential.

Terms and Conditions

Pregnancy Category D: There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks. Drugs in this category include tramadol and gabapentin. They should be prescribed in pregnancy only when benefit clearly outweighs risk.

Pregnancy Category X: Studies in animals or humans have demonstrated fetal abnormalities or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits. Drugs such as warfarin, methotrexate, and statins fall into this category and must not be used during pregnancy or in women likely to become pregnant.

Physicians should realize that the pregnancy categories by themselves provide little guidance for the physician treating pregnant women. Prescribers must understand the embryology, physiology, and pharmacology involved in each instance of drug use during pregnancy. For example, ACE inhibitors such as captopril cause developmental toxicity (category X), but only after the first trimester. A physician’s primary responsibility remains treating the pregnant patient. However, the risks of withholding treatment to the mother because of possible risks to the fetus have to be considered as well. The practitioner should rely on medical evidence when making these decisions.

Drugs also are grouped by their potential for misuse under British and U.N. legal classifications as class A, B, or C. The classes are linked to maximum legal penalties in a descending order of severity, from A to C.

Suggestions for Improving Patient Compliance

- Provide respectful communication; ask how patient takes medicine.
- Develop satisfactory, collaborative relationship between physician and patient; encourage pharmacist involvement.
- Provide and encourage use of medication counseling.
- Give precise, clear instructions, with most important information given first.
- Support oral instructions with easy-to-read written information.
- Simplify whenever possible.
- Use mechanical compliance aids as needed (sectioned pillboxes or trays, compliance packaging, color coding).
- Use optimal dosage form and schedule for each individual patient.
- Assess patient’s literacy, language, and comprehension and modify educational counseling as needed. Be culturally aware and sensitive. To improve compliance, don’t rely on patient’s own knowledge of disease alone.
- Find solutions when physical or sensory disabilities are present (use nonsafety caps on bottles, use large type on labels and written material, place tape marks on syringes).
- Enlist support and assistance from family and caregivers.
- Use behavioral techniques such as goal setting, self-monitoring, cognitive restructuring, skills training, contracts, and positive reinforcement.

When deciding on a course of therapy, it can be useful to discuss a patient’s habits and daily routine as well as the therapeutic options with the patient. This information may suggest cues for remembrance. A lack of information about a patient’s lifestyle can lead to situations such as prescribing a medication to be taken with meals three times daily for a patient who only eats twice a day or a medication to be taken each morning for a patient who works a night shift and sleeps during the day. Rarely is there only one treatment option for a given problem, and it may be better to prescribe an adequate regimen that the patient will follow instead of an ideal regimen that the patient will not. Attempts should be made to resolve collaboratively any conflicts that may hinder compliance. Whenever possible, the family should be aware of the physician’s treatment plan in order to assist with compliance.

Patients and Their Beliefs

Patients are more likely to be compliant when they perceive that they are susceptible to the disease, that the disease may have serious negative impact, that the therapy will be effective, that the benefits outweigh the costs, and when they believe in their own ability to execute the therapy. The actual severity of and susceptibility to an illness are not necessarily an issue; rather, the patient’s perception of severity affects compliance. Patients’ beliefs can lead them to deliberately alter their therapy; whether for convenience, for personal experiments, because of a desire to remove themselves from the sick role, as a means to exercise a feeling of control over their situation, or for other reasons. This reinforces the need for precise communication and a good patient-provider relationship to facilitate the provision of additional or corrective education when the beliefs would suggest poor compliance as an outcome (Hsiao et al., 2012; Nieuwlaat et al., 2014).

Pharmacists have a legal and professional responsibility to offer medication counseling and can educate and support patients by discussing prescribed medications and their use. Because they often see the patient more frequently than does the physician, pharmacists who take the time to inquire about a patient’s therapy can help identify compliance and other problems, educate the patient, and notify the physician as appropriate (Phatak et al., 2016). Indeed, data from the Asheville Project indicates that a pharmacist-based medication management program provides significant advantages with respect to compliance, health outcomes, and cost (Bunting and Cranor, 2006).
Include patient age and weight on the prescription, when appropriate, to ensure safety be ensured.

Mutual responsibilities are front and center in their minds will patient compliance. Physicians and pharmacists must remember that only when the seriousness of their personal attention to the individual patient by healthcare workers but rather than any other age group pharmacists must be careful in choosing medications for the elderly. Physicians must pay particular attention to thorough and compassionate counseling for elderly patients and should assist patients in finding practical solutions when problems, such as polypharmacy, are noted (Mansur, 2016).

The Therapy

Increased complexity and duration of therapy are perhaps the best-documented barriers to compliance. The patient for whom multiple drugs are prescribed for a given disease or who has multiple illnesses that require drug therapy will be at higher risk for noncompliance, as will the patient whose disease is chronic. The frequency of dosing of individual medications also can affect compliance behavior. Simplification, whenever possible and appropriate, is desirable.

The effects of the medication can make adherence less likely, as in the case of patients whose medicines cause confusion or other altered mental states. Unpleasant side effects from the medicine may influence compliance in some patients, but are not necessarily predictive, especially if patient beliefs or other positive factors tend to reinforce adherence to the regimen. A side effect that is intolerable to one patient may be of minor concern to another. The cost of medicine can be a heavy burden for patients with limited economic resources, and healthcare providers should be sensitive to this fact (Restrepo et al., 2008). Mobile phones and tablets running drug formulary/therapeutic applications can provide the costs of medications, as can physicians who are familiar with the patient’s insurance plan. Mobile phone systems and wearables that provide reminders and collect patient response information and physiological data are being introduced and may become more popular as patients and providers become increasingly tech savvy (Parmanto et al., 2013). Such technology may soon be capable of carrying patient genetic information that may assist the physician in choosing medications based on knowledge of a patient’s ability to metabolize a specific drug efficiently or that such treatment may interfere with an existing treatment (Weiss and Shin, 2016). Effective treatments that do not produce unwanted effects will improve compliance.

Electronic Prescribing

The era of e-prescribing eliminates some of the subjective features of prescribing. Thus, if the proper information is entered correctly in the electronic system, medication errors due to illegible handwriting, incorrect dose, incorrect medication for medical condition, and drug interactions can be reduced. Electronic prescriptions can be linked to high-quality drug databases that check that the information on the prescription is appropriate for the patient (e.g., age, weight, gender, condition, laboratory values, disease being treated, concurrent medications) and that known warnings and potential problems are brought to the attention of the physician, pharmacist, and patient. Such systems must not be used as a substitute for personal attention to the individual patient by healthcare workers but rather as an adjunct measure that ensures safe, high-quality, efficient care. Sadly, the participation of human beings in the process has not eliminated errors, even in the university hospital setting (Al Tehewy et al., 2016). Physicians and pharmacists must remember that only when the seriousness of their mutual responsibilities are front and center in their minds will patient safety be ensured.

Eliminating Errors in Drug Orders

The IOM estimates that the annual number of medical errors in the U.S. that result in death is between 44,000 and 98,000 (Kohn, 2001). Although there is some controversy about these estimates, it is clear that the large number of medical errors includes medication errors resulting in adverse events, including death. Databases of anonymously reported errors are maintained jointly by the ISMP, the USP MIERP, and the FDA’s MedWatch program. Adverse drug events occur in about 3% of hospitalizations, and this number is larger for special populations, such as those in pediatric and neonatal intensive care units. By examining aspects of prescription writing that can cause errors and then modifying prescribing habits accordingly, the physician can increase the probability that the patient will receive the correct prescription. By being alert to common problems that can occur with medication orders and communicating with the patient’s physician, pharmacists and other healthcare professionals can assist in reducing medication errors. Proper prescribing practices (Box AI–3) can help to prevent adverse drug events.

BOX AI–3  Prescribing Practices to Avoid Adverse Drug Events

- Write all orders legibly using metric measurements of weight and volume.
- Include patient age and weight on the prescription, when appropriate, so dosage can be checked.
- Use Arabic (decimal) numerals rather than Roman numerals (e.g., does “IL–II” mean “IL–11” or “IL–2?”); in some instances, it is preferable for numerals to be spelled out.
- Use leading zeros (0.125 milligrams, not .125 milligrams); never use trailing zeros (5 milligrams, not 0.5 milligrams).
- Avoid abbreviating drug names; abbreviations may lead to misinterpretation.
- Avoid abbreviating directions for drug administration; write out directions clearly in English.
- Be aware of possibilities for confusion in drug names. Some drug names sound alike when spoken and may look alike when spelled out. The U.S. Pharmacopeial Convention Medication Errors Reporting Program maintains a current list of 750 drug names that can be confused (http://www.usp.org). Allotropic drug names can be particularly problematic when giving verbal orders to pharmacists or other healthcare providers.
- Provide the patient’s diagnosis on the prescription order to prevent dispensing errors based on sound-alike or look-alike drug names. For example, an order for administration of magnesium sulfate must not be abbreviated “MS,” as this may result in administration of morphine sulfate. Including the therapeutic purpose or the patient’s diagnosis can prevent this error.
- Write clearly. Both physician and pharmacist share in the responsibility for preventing adverse drug events by writing prescriptions clearly (When in doubt, write it out!) and questioning intent whenever an order is ambiguous (When in doubt, check it out!). Pharmacists must clarify their concerns with prescribers, not patients.
- Think.
- Think again.

Bibliography

Bunting BA, Cranor CW. The Asheville Project: long-term clinical, humanistic, and economic outcomes of a community-based medication...
This page intentionally left blank
This appendix provides a summary of basic pharmacokinetic information pertaining to small-molecule drugs that are in common clinical use and are delivered to the systemic circulation by parenteral or nonparenteral administration. Because of space limitations, this list cannot be exhaustive. Drugs designed exclusively for topical administration and not to be significantly absorbed into the bloodstream (e.g., ophthalmic and some dermal applications; Chapters 69 and 70) are not included. A few other selection criteria have influenced the makeup of the list, but, in general, the authors have tried to include one or more representative drugs in each of the therapeutic areas in this text, based on distinct mechanism(s) of action. In some instances, drugs may be excluded because pharmacokinetics are not relevant to their therapeutic management. An obvious case is when drug efficacy is not apparently correlated with drug concentration in a reversible fashion (e.g., some cytotoxic anticancer drugs).

Often, the issue comes down to deciding which of the many drugs within a class should be selected. This is particularly problematic when the choices are largely therapeutic equivalents. Two criteria that have proven useful are prevalence of use and uniqueness of mechanism of action. For the present edition, we have consulted the top 200 selling drugs in 2015 for usage data. Drugs that fall into that list and meet the criteria mentioned were generally selected. We have also consulted all new FDA drug approvals between 2010 and 2015. As mentioned, a drug used less may be included if it has a different mechanism of action than the frequently used drugs, some additional actions that offer a unique therapeutic advantage, or a more acceptable side-effects profile. Pharmacokinetic data for many older drugs not included in this appendix can be found in earlier editions of this book.

With rare exceptions (e.g., interferons), recombinant therapeutic proteins have been excluded from this compilation. In many cases, the therapeutic protein is directed to interact with specific tissue or cellular targets with exquisite affinity; as a result, clinical efficacy seldom correlates with circulating drug concentration, and pharmacokinetics are not considered critical in guiding its dosing. For example, for a number of therapeutic antibodies, the antibody is administered at a fixed dose at prolonged intervals that allow for its near-complete clearance (e.g., infliximab). There is again the constraint of space limitation; hence, it was decided that the appendix should focus on small-molecule drugs.

A major objective of this appendix is to present pharmacokinetic data in a format that informs the clinician of the essential characteristics of drug disposition that form the basis of drug-dosage regimen design. Table AII–1 contains quantitative information about the absorption, distribution, and elimination of drugs; the effects of some disease states, age, pregnancy, and gender on these processes, where significant; and the correlation of efficacy and toxicity with drug concentrations in blood/plasma. The general principles that underlie the design of appropriate maintenance dose and dosing interval (and, where appropriate, the loading dose) for the average patient are described in Chapter 2. Their application using the data in Table AII–1 for individualization of dosage regimens is presented here.

To use the data that are presented, one must understand clearance concepts and their application to drug-dosage regimens. One also must know average values of clearance as well as some kinetic measures of drug absorption and distribution. The text that follows defines the eight basic parameters that are listed in the tabular material for each drug and key factors that influence these values in both normal subjects and patients with renal or liver disease. It obviously would be more straightforward if there were a consensus on a standard value for a given pharmacokinetic parameter; instead, literature estimates usually vary over a wide range, and a consensus set of pharmacokinetic values has been reached for only a limited number of drugs.

In Table AII–1, a single set of values for each parameter and its variability in a relevant population has been selected from the literature, based on the scientific judgment of the authors. Most data are in the form of a study population mean value ± 1 standard deviation (mean ± SD). However, some data are presented as mean and range of values (in parentheses) observed for the study population (i.e., the lowest and highest value reported). There are times when data are reported as a geometric mean with a 95% confidence interval or a coefficient of variation (in percentage). If sufficient data were available, we present a range of mean values obtained from different studies of similar design in parentheses, sometimes below the primary study data. Occasionally, only a single mean value for the study population was available in the literature and is reported as such. Finally, some drugs can be administered intravenously in an unmodified form and orally as a prodrug. When relevant information about both the prodrug and the active molecule are needed, we have included both, using an abbreviation to indicate the species that was measured, followed by another abbreviation in parentheses to indicate the species that was dosed [e.g., G (V) indicates a parameter for ganciclovir after administration of the prodrug, valganciclovir].

A number of approved drugs are actually the active metabolite or stereoisomer of an earlier marketed drug. For example, desloratadine is the O-desmethyl metabolite of loratadine, and esomperazol is the active S-enantiomer of omeprazol. Unless the parent drug and the active metabolite offer distinct therapeutic advantages, only the more established or more commonly used drug is listed, and relevant information on its alternate active form is presented in the same table. This approach has
permits us to include more drugs in the appendix, it is hoped without undue confusion. The only exception is with prednisone and prednisolone, which undergo interconversion in the body.

Unless otherwise indicated in footnotes, data reported in the table are those determined in healthy adults. The direction of change for these values in particular disease states is noted below the average value. In previous editions, we have included disease states where studies have shown no change or clinically insignificant change for a particular pharmacokinetic measure. For the sake of space and consistency, we have eliminated the results of negative studies; hence, when a disease state is not listed, it implies no significant change or no information is available. One or more references are provided for each of the established drugs, typically an original journal publication, a review on its clinical pharmacokinetics, or web-based drug database; the last two secondary sources provide a broader range of papers for the interested reader. In some instances (e.g., many new drug approvals), we have relied on unpublished data provided by the drug sponsor in its NDA files or package labeling submitted to the U.S. FDA. This information can be accessed at Drugs@FDA: FDA Approved Drug Products (https://www.accessdata.fda.gov/scripts/cder/daf/). After searching by drug name, pharmacokinetic data are found most often in the Clinical Pharmacology and Biopharmaceutics section. Recent standardization in the presentation of data supporting the NDA in this section makes this an increasingly valuable resource.

**Tabulated Pharmacokinetic Parameters**

Each of the eight parameters presented in Table AII–1 was discussed in Chapter 2. The following discussion focuses on the format in which the values are presented as well as on physiological or pathological factors that influence the parameters.

**Bioavailability**

The *extent of oral bioavailability* is expressed as a percentage of the administered dose. This value represents the percentage of the administered dose that is available to the systemic circulation—the fraction of the oral dose that reaches the arterial blood in an active or prodrug form, expressed as a percentage (0–100). *Fractional availability* \( F \), which appears elsewhere in this appendix, denotes the same parameter; this value varies from 0 to 1. *Clearance* as a measure of the *rate of availability* is also presented in the table. The extent of availability is needed for the design of an oral dosage regimen to achieve a specific target blood concentration. Values for multiple routes of administration are provided, when appropriate and available. In most cases, the tabulated value represents an absolute oral bioavailability that has been determined from a comparison of AUC between the oral dose and an intravenous reference dose. For those drugs for which intravenous administration is not feasible, an approximate estimate of oral bioavailability based on secondary information (e.g., urinary excretion of unchanged drug, especially when the nonrenal route of elimination is minimal) is presented, or the column is left blank (denoted by a long dash [—]). A dash also will appear when a drug is given by parenteral administration only. A low oral bioavailability may result from a poorly formulated dosage form that fails to disintegrate or dissolve in the gastrointestinal fluid; has degradative loss of drug in the gastrointestinal fluid; has poor mucosal permeability, including active efflux transport of drug back into the lumen; has first-pass metabolism during transit through the intestinal epithelium; or there is first-pass hepatic metabolism or biliary excretion (see Chapter 2). In the case of drugs with extensive first-pass metabolism, hepatic disease may increase oral availability because hepatic metabolic capacity decreases or because vascular shunts develop around the liver.

**Urinary Excretion of Unchanged Drug**

The second parameter in Table AII–1 is the amount of drug eventually excreted unchanged in the urine, expressed as a percentage of the administered dose. Values represent the percentage expected in a healthy young adult (creatinine clearance \( \geq 100 \text{ mL/min} \)). When possible, the value listed is that determined after bolus intravenous administration of the drug, for which bioavailability is 100%. If the drug is given orally, this parameter may be underestimated due to incomplete absorption of the dose; such approximated values are indicated with a footnote. The parameter obtained after intravenous dosing is of greater utility because it reflects the fractional contribution of renal clearance to total body clearance irrespective of bioavailability.

Renal disease is the primary factor that causes changes in this parameter. This is especially true when alternate pathways of elimination are available; thus, as renal function decreases, a greater fraction of the dose is available for elimination by other routes. Because renal function generally decreases as a function of age, the percentage of drug excreted unchanged also decreases with age when alternate pathways of elimination are available. In addition, for a number of weakly acidic and basic drugs with \( pK_a \) values within the normal range for urine \( \text{pH} \), changes in urine \( \text{pH} \) will affect their rate or extent of urinary excretion (see Chapter 2).

**Binding to Plasma Proteins**

The tabulated value is the percentage of drug in the plasma that is bound to plasma proteins at concentrations of the drug that are achieved clinically. In almost all cases, the values are from measurements performed in vitro (rather than from ex vivo measurements of binding to proteins in plasma obtained from patients to whom the drug had been administered). When a single mean value is presented, it signifies that there is no apparent change in percentage bound over the range of plasma drug concentrations resulting from the usual clinical doses. In cases in which saturation of binding to plasma proteins is approached within the therapeutic range of plasma drug concentrations, a range of bound percentages is provided for concentrations at the lower and upper limits of the range. For some drugs, there is disagreement in the literature about the extent of plasma-protein binding; in those cases, the range of reported values is given.

Plasma-protein binding is affected primarily by disease states, notably hepatic disease, renal impairment, and inflammatory diseases, that alter the concentration of albumin, \( \alpha_1 \)-acid glycoprotein, or other proteins in plasma that bind drugs. Uremia also changes the apparent binding affinity of albumin for some drugs. Disease-induced changes in plasma-protein binding can dramatically affect the volume of distribution, clearance, and elimination \( t_{1/2} \) of a drug. In regard to clinical relevance, it is important to assess the change in unbound drug concentration or AUC, particularly when only unbound drug can cross biological barriers and gain access to the site of action.

**Plasma Clearance**

Systemic clearance of total drug from plasma or blood (see Equations 2–4, 2–5, and 2–7 in Chapter 2) is given in Table AII–1. Clearance varies as a function of body size and therefore most frequently is presented in the table in units of milliliters/minute/kilogram of body weight. Normalization to measures of body size other than weight may at times be more appropriate, such as normalization to body surface area in infants to better reflect the growth and development of the liver and kidneys. However, weight is easy to obtain, and its use often offsets any small loss in accuracy of clearance estimate, especially in adults. Exceptions to this rule are the anticancer drugs, for which dosage normalization to body surface area is
conventionally used. When unit conversion was necessary, we used individual or mean body weight or body surface area (when appropriate) from the cited study, or if this was not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

For the few drugs that exhibit saturation kinetics following therapeutics doses, \( K_e \) and \( V_\text{ms} \) are given and represent, respectively, the plasma concentration at which half of the maximal rate of elimination is reached (in units of mass/volume) and the maximal rate of elimination (in units of mass/time/kilogram of body weight). \( K_e \) must be in the same units as the concentration of drug in plasma (\( C_P \)).

In almost all cases, clearances based on plasma concentration data are presented in Table AII–1 because drug analysis most often is performed on plasma samples. The few exceptions where clearance from blood is indicated are noted by footnote. Clearances estimates based on blood concentration may be useful when a drug concentrates in the blood cells.

To be accurate, clearances must be determined after intravenous drug administration. When only nonparenteral data are available, the ratio of \( CL/F \) is given; values offset by the fractional availability \( F \) are indicated in a footnote. When a drug, or its active isomer for racemic compounds, is known to be a substrate for a CYP or drug transporter, this information is provided in a footnote. This information is important for understanding pharmacokinetic variability due to genetic polymorphisms and for predicting metabolically based drug-drug interactions, although these factors are beyond the scope of this table. For clinically relevant pharmacogenetic information, the reader is referred to CPIC Guidelines listed on the PharmGKB website (https://www.pharmgkb.org/). The reader is referred to a comprehensive database for drug-drug interaction information (DIDDB) (https://www.druginteractioninfo.org/). The former site is open access, whereas the latter can be accessed by a licensing agreement.

**Volume of Distribution**

The total body volume of distribution at steady state \( V_\text{ss} \) is given in Table AII–1 and is expressed in units of liters/kilogram or in units of liters/square meter for some anticancer drugs. Again, when unit conversion was necessary, we used individual or mean body weights or body surface area (when appropriate) from the cited study, or if such data were not available, we assumed a body mass of 70 kg or a body surface area of 1.73 m² for healthy adults.

When estimates of \( V_\text{ss} \) were not available, values for \( V_\text{ms} \) are provided; \( V_\text{ss} \) represents the volume at equilibrated distribution during the terminal elimination phase. Unlike \( V_\text{ss} \), \( V_\text{ms} \) varies when drug elimination changes, even though there is no change in extravascular distribution. Because we may wish to know whether a particular disease state influences either the clearance or the tissue distribution of the drug, it is preferable to define volume in terms of \( V_\text{ss} \), a parameter that is less likely to depend on changes in the rate of elimination. Occasionally, the condition under which the distribution volume was obtained was not specified in the primary reference; this is denoted by the absence of a subscript.

As with clearance, \( V_\text{ss} \) usually is defined in the table in terms of concentration in plasma rather than blood. Further, if data were not obtained after intravenous administration of the drug, a footnote will make clear that the apparent volume estimate, \( V_\text{ss}/F \) or \( V_\text{ms}/F \), is offset by the fractional availability.

**Half-Life**

Half-life \( t_{1/2} \) is the time required for the plasma concentration to decline by one-half when elimination is first order. It also governs the rate of approach to steady state and the degree of drug accumulation during multiple dosing or continuous infusion. For example, at a fixed dosing interval, the patient will be at 50% of steady state after one half-life, 75% of steady state after two half-lives, 93.75% of steady state after four half-lives, and so on. Determination of \( t_{1/2} \) is straightforward when drug elimination follows a monoexponential pattern (i.e., one-compartment model). However, for a number of drugs, plasma concentration follows a multieponential pattern of decline over time. The mean value listed in Table AII–1 corresponds to an effective rate of elimination that covers the clearance of a major fraction of the absorbed dose from the body. In many cases, this \( t_{1/2} \) refers to the rate of elimination in the terminal exponential phase. For a number of drugs, however, the \( t_{1/2} \) of an earlier phase is presented, even though a prolonged \( t_{1/2} \) may be observed later at very low plasma concentrations when extremely sensitive analytical techniques are used. If the latter component accounts for 10% or less of the AUC, predictions of drug accumulation in plasma during continuous or repetitive dosing will be in error by no more than 10% if this longer \( t_{1/2} \) is ignored. Equation 2–19 in Chapter 2 provides for an estimate of the effective \( t_{1/2} \) that predicts time to steady state for multicompartamental drug kinetics. It is this \( t_{1/2} \) of accumulation during multiple dosing that is given in Table AII–1.

Half-life is usually independent of body size because it is a function of the ratio of two parameters, clearance and volume of distribution, each of which is proportional to body size. It also should be noted that the \( t_{1/2} \) is preferably obtained from intravenous studies, if feasible, because the \( t_{1/2} \) of decline in plasma drug concentration after oral dosing can be influenced by prolonged absorption, such as when slow-release formulations are given. If the \( t_{1/2} \) is derived from an oral dose, this will be indicated in a footnote of Table AII–1.

**Time to Peak Concentration**

Because clearance concepts are used most often in the design of multiple-dose regimens, the extent rather than the rate of availability is more critical to estimate the average steady-state concentration of drug in the body. In some circumstances, the extent of fluctuation in plasma drug concentration (i.e., peak and trough concentrations), which govern drug efficacy and side effects, can be greatly influenced by modulation of drug absorption rate through the use of sustained- or extended-release formulations. Controlled-release formulations often permit a reduction in dosing frequency from three or four times daily to once or twice daily. There also are drugs that are given on an acute basis (e.g., for the relief of breakthrough pain or to induce sleep), for which the rate of drug absorption is a critical determinant of onset of effect. Thus, information about the expected average time to achieve maximal plasma or blood concentration and the degree of interindividual variability in that parameter have been included in Table AII–1.

The time required to achieve a maximal concentration \( C_{\text{max}} \) depends on the rate of drug absorption into blood from the site of administration and the rate of elimination. From mass balance principles, \( C_{\text{max}} \) occurs when the rate of absorption equals the rate of elimination from the reference compartment. Prior to this time, absorption rate exceeds elimination rate, and the plasma concentration of drug increases. After the peak is reached, elimination rate exceeds the absorption rate and, at some point, defines the terminal elimination phase of the concentration-time profile. The rate of drug absorption following oral administration will depend on the formulation and physicochemical properties of the drug, its permeability across the mucosal barrier, and the intestinal villous blood flow. For an oral dose, some absorption may occur very rapidly within the buccal cavity, esophagus, and stomach, or absorption may be delayed until the drug reaches the small intestine or until the local pH in the intestine permits drug release from the dosage formulation. In the most extreme case, the rate of absorption can be sufficiently controlled by the drug formulation to permit sustained or extended delivery as the dosage form traverses the entire length of the gastrointestinal tract. In some instances, the terminal elimination of drug from the body following a peak concentration reflects the slower rate of absorption and not elimination.

When more than one type of drug formulation is available commercially, we provide absorption information for both the immediate- and extended-release formulations. Not surprisingly, the presence of food in the gastrointestinal tract can alter both the rate and the extent of drug availability. We indicate with footnotes when the consumption of food near the time of drug ingestion may have a significant effect on the drug bioavailability.

**Peak Concentration**

There is no general agreement about the best way to describe the relationship between the concentration of drug in plasma and its effect. Many different kinds of data are present in the literature, and use of a single-effect
have been introduced within the past 15 years. In some cases, a significant deviation from the manufacturer’s recommendation in the package labeling when available is necessary to infer therapeutic concentrations from concentration-time curves, when the drug concentration(s) at the site(s) of action are expected to parallel those in plasma. Thus, when attempting to correlate a blood or plasma level to effect, the temporal aspect of distribution of drug to its site of action must be taken into account.

Despite these limitations, it is possible to define the minimum effective or toxic concentrations for some of the drugs currently in clinical use. However, in reviewing the list of drugs approved within the past 5 years, it is rare to find a declaration of an effective concentration range, even in the manufacturer’s package labeling. Thus, it is necessary to infer therapeutic concentrations from concentrations observed following effective dosage regimens. For a given dosage regimen, a time-averaged steady-state blood or plasma concentration (i.e., \( C_{\text{ss}} \)) can be estimated as the ratio of the mean AUC by the duration of the dosing interval and the associated interindividual variability might be one appropriate parameter to report; however, such data often are not available. Also, \( C_{\text{ss}} \) does not take into account the onset and offset of effect during fluctuation of plasma drug concentration over a dosing interval. In some instances, drug efficacy may be more closely linked with peak concentration than with the average or trough concentration, and differences in peak concentration for special populations (e.g., elderly) sometimes are associated with increased incidence of drug toxicity.

For practical reasons, the most commonly reported parameter, \( C_{\text{max}} \) (peak concentration), rather than effective or toxic concentrations, is presented in Table AII–1. This provides a more consistent body of information about drug exposure from which one can infer, if appropriate, efficacious or toxic blood levels. Although the value reported is the highest that would be encountered in a given dose interval, \( C_{\text{max}} \) can be related to the trough concentration \( C_{\text{min}} \) through appropriate mathematical predictions (see Equation 2–20 in Chapter 2). Because peak levels will vary with dose, we have attempted to present concentrations observed with a customary dose regimen that is recognized to be effective in the majority of patients. When a higher or lower dose rate is used, the expected peak level can be adjusted by assuming dose proportionality, unless nonlinear kinetics are indicated. In some instances, only limited data pertaining to multiple dosing are available, so single-dose peak concentrations are presented. When specific information is available about an effective therapeutic range of concentrations or about concentrations at which toxicity occurs, it has been incorporated in a footnote.

It is important to recognize that significant differences in \( C_{\text{max}} \) will occur when comparing similar daily-dose regimens for an immediate-release and extended-release product. Indeed, the extended-release product sometimes is administered to reduce peak-trough fluctuations during the dosing interval and to minimize swings between potentially toxic or ineffective drug concentrations. Again, we report \( C_{\text{max}} \) for both immediate- and extended-release formulations, when available. In addition to parent drug concentrations, we have included information on any active metabolite that circulates at a concentration that may contribute to the overall pharmacological effect, particularly those active metabolites that accumulate with multiple dosing. Likewise, for chiral drugs whose stereoisomers differ in their pharmacological activity and clearance characteristics, we present information on concentrations of the individual enantiomers or the active enantiomer that contributes most to the drug’s efficacy.

### APPENDIX II
DESIGN AND OPTIMIZATION OF DOSAGE REGIMENS: PHARMACOKINETIC DATA

#### Alterations of Parameters in the Individual Patient

Dose adjustments for an individual patient should be made according to the manufacturer’s recommendation in the package labeling when available. This information generally is available when disease, age, or race has a significant impact on drug disposition, particularly for drugs that have been introduced within the past 15 years. In some cases, a significant difference in drug disposition from the “average” adult can be expected but may not require dose adjustment because of a sufficiently broad therapeutic index. In other cases, dose adjustment may be necessary, but no specific information is available. Under these circumstances, an estimate of the appropriate dosing regimen can be obtained based on pharmacokinetic principles described in Chapter 2.

Unless otherwise specified, the values in Table AII–1 represent mean values for populations of normal adults; it may be necessary to modify them for calculation of dosage regimens for individual patients. The fraction available \( F \) and clearance \( CL \) would need to be adjusted to compute a maintenance dose necessary to achieve a desired average steady-state concentration. To calculate the loading dose, knowledge of the volume of distribution is needed. The estimated \( t_{1/2} \) is used in deciding a dosing interval that provides an acceptable peak-trough fluctuation; note that this may be the apparent \( t_{1/2} \) following dosing of a slowly absorbed formulation. The values reported in the table and the adjustments apply only to adults; exceptions are footnoted. Although the values at times may be applied to children who weigh more than about 30 kg (after proper adjustment for size; see Clearance and Volume of Distribution, presented in the following material), it is best to consult pediatric textbooks or other sources for definitive advice.

For each drug, changes in the parameters caused by certain disease states are noted within the eight segments of the table. In all cases, the qualitative directional changes of changes is noted, such as “\( \downarrow \) LD,” which indicates a significant decrease in the parameter in a patient with chronic liver disease. The relevant literature and the package label should be consulted for more definitive, quantitative information for dosage adjustment recommendations.

## Plasma Protein Binding

Most acidic drugs that are extensively bound to plasma proteins are bound to albumin. Basic lipophilic drugs, such as propranolol, often bind to other plasma proteins (e.g., α- and β-acid glycoprotein and lipoproteins). The degree of drug binding to proteins will differ in pathophysiological states that cause changes in plasma protein concentrations. Significant pharmacokinetic effects from a change in plasma protein binding are denoted under clearances or volume of distribution.

Although pharmacokinetic parameters based on total drug or metabolite concentrations often are reported, it is important to recognize that in many cases it is the concentration of unbound drug that drives access to the site of action and the degree of pharmacological effect. Remarkable changes in the total plasma concentration may accompany disease-induced alteration in protein binding; however, the clinical outcome is not always affected because an increase in free fraction also will increase the apparent clearance of an orally administered drug and of a low-extraction drug dosed intravenously. Under such a scenario, the time-averaged unbound plasma concentration over a dosing interval at steady state will not change with reduced or elevated plasma protein binding, despite a significant change in time-averaged total drug concentration. If so, no adjustment of daily maintenance dose is needed.

### Clearance

For drugs that are partly or predominantly eliminated by renal excretion, plasma clearance changes in accordance with the renal function of an individual patient. This necessitates dosage adjustment that is dependent on the fraction of normal renal function remaining and the fraction of drug normally excreted unchanged in the urine. The latter quantity appears in the table; the former can be estimated as the ratio of the patient’s estimated or measured creatinine clearance \( CL_{\text{cr}} \) to a normal value (100 mL/min/1.73 m²). Because creatinine clearance is not routinely measured, it is often estimated from standardized serum creatinine concentration \( C_{\text{s}} \) using the MDRD Study equation for \( CL_{\text{cr}} \) less than 60 mL/min/1.73 m².

\[
CL_{\text{cr}} \text{(mL/min/1.73 m²)} = 175 \times C_{\text{s}}^{-1.154} \times (\text{Age})^{-0.203} \times (0.742 \text{ if female}) \times (1.212 \text{ if African American}) \quad (\text{Equation A–1})
\]

Note that Equation A–1 does not require body weight as the \( CL_{\text{cr}} \) estimate is normalized to average adult body surface; proportionate

\[\text{[bruntont_app_ii_p1325p1378.indd] 1328}\]
scaling is needed for adjustment to a different body surface area. Convenient calculators are available for the MDRD equation and the CKD-EPI equation for more accurate estimation of CL, >60 mL/min/1.73 m² (e.g., https://www.niddk.nih.gov/health-information/health-communication-programs/nkdep/lab-evaluation/gfr/estimating/Pages/estimating.aspx).

The fraction of normal renal function rfxₚᵣ is estimated from the following:

\[ rfx_{pt} = \frac{CL_{pt}}{100 \text{ mL/min}} \]  
(Equation A–2)

A more accurate measure of rfxₚᵣ seldom is necessary because, given the considerable degree of interindividual variation in nonrenal clearance, the adjustment of clearance is an approximation. The following equation for adjustment of clearance uses the quantities discussed:

\[ rfx_{pt} = 1 - (fe_{pt} \times (1 - rfx_{pt})) \]  
(Equation A–3)

where feₚᵣ is the fraction of systemic drug excreted unchanged in normal individuals (see Table AII–1). The renal factor rfxₚᵣ is the value that, when multiplied by normal total clearance CL, gives the total clearance of the drug adjusted for the impairment in renal function.

**Example**

The clearance of vancomycin in a patient with reduced renal function (creatinine clearance = 25 mL/min for an average-size adult) may be estimated as follows:

\[ rfx_{pt} = \frac{25 \text{ mL/min}}{100 \text{ mL/min}} = 0.25 \]
\[ fe_{pt} = 0.79 \text{ (see listing for vancomycin)} \]
\[ rf_{pt} = 1 - (0.79 \times (1 - 0.25)) = 0.41 \]
\[ CL_{pt} = (1.3 \text{ mL/min/kg}) \times 0.41 \]
\[ = 0.53 \text{ mL/min/kg} \]

Importantly, such a clearance adjustment should be regarded only as an initial step in optimizing the dosage regimen; depending on the patient’s response to the drug, further individualization may be necessary.

Conventionally, clearance is adjusted for the size of the patient to reflect a difference in the mass of the eliminating organ. For orally administered drugs, the applicability of such an adjustment may be limited by the available dosage strengths of commercial formulations. In some cases, scored tablets can be split, or commercial tablet splitters are used to increase the range of available dosage strengths. However, this practice should be followed only with the recommendation of the pharmacist because splitting a tablet sometimes can compromise the bioavailability of a product.

With the exception of certain oncolytic agents, the data presented in the table are normalized to weight. Thus, interindividual variability in the weight-normalized clearance reflects a variation in the intrinsic metabolic or transport clearance and not the size of the organ. Further, these differences can be attributed to variable expression/function of metabolic enzymes or transporters. However, it is important to recognize that liver mass and total enzyme/transporter content may not increase or decrease in proportion to weight in obese or malnourished individuals. Alternative approaches such as normalization by body surface area or other measures of body mass may be more appropriate. For example, many of the drugs used to treat cancer are dosed according to body surface area (see Chapters 65 and 66). In the tabulation, if the literature reported dose per body surface area, we present the data in the same unit. If the cited clearance data were not normalized, but the preponderance of the literature utilized body surface area, we followed the practice of using values of body surface area from the literature source or a standard of 1.73 m² for a healthy adult.

**Volume of Distribution**

Volume of distribution should be adjusted for the modifying factors indicated in Table AII–1 as well as for body size. Again, the data in the table most often are normalized to weight. Unlike clearance, volume of distribution in an individual usually is proportional to weight itself. Whether this applies to a specific drug depends on the actual sites of distribution of drug; no absolute rule applies.

Whether to adjust volume of distribution for changes in binding to plasma proteins cannot be decided in general; the decision depends critically on whether the factors that alter binding to plasma proteins also alter binding to tissue proteins. Qualitative changes in volume of distribution, when they occur, are indicated in the table.

**Half-Life**

Half-life may be estimated from the adjusted values of clearance CL, and volume of distribution V, for the patient:

\[ t\frac{1}{2} = \frac{0.693 \times V_{pt}}{CL_{pt}} \]  
(Equation A–4)

Because t₁/₂ has been the parameter most often measured and reported in the literature, qualitative changes for this parameter almost always are given in the table.

**Individualization of Dosage**

By using the parameters for the individual patient, calculated as described in the previous section, initial dosing regimens may be chosen. The maintenance dosage rate may be calculated with Equation 2–17 in Chapter 2, using the estimated values for CL and F for the individual patient. As described previously, the target concentration may have to be adjusted for changes in plasma protein binding in the patient, as described in Plasma Protein Binding. The loading dose may be calculated using Equation 2–21 and estimates for V, and F. A particular dosing interval may be chosen; the maximal and minimal steady-state concentrations can be calculated by using Equations 2–20, and these calculated concentrations can be compared with the known efficacious and toxic concentrations for the drug. As with the target concentration, these values may need to be adjusted for changes in the extent of plasma protein binding. Use of Equations 2–20 and 2–21 also requires estimates of values for F, V, and K (K = 0.693/t₁/₂) for the individual patient.

Note that these adjustments of pharmacokinetic parameters for an individual patient are suggested for the rational choice of initial dosing regimen. As indicated in Chapter 2, steady-state measurement of drug concentrations in the patient then can be used as a guide to further adjust the dosage regimen. However, optimization of a dosage regimen for an individual patient ultimately will depend on the clinical response produced by the drug.

<sup>a</sup>Bupropion is administered as a racemic mixture of R and S bupropion that can interconvert. Data from healthy adult male volunteers. Bupropion is metabolized by CYP2B6 to hydroxy-bupropion and by 11β-hydroxysteroid-dehydrogenase and aldo-ketorucetidases to three- and erythrohydrobupropion. All three metabolites accumulate in blood and are active. CL/F, \(V_{\text{ss}}/<F\), and \(t_{\text{1/2}}\) reported for oral dose. Percentage coefficient of variation shown in parentheses. Following oral dosing of 150 mg XL (sustained release) tablet to 42 healthy subjects for 7 days (steady state). 95% confidence interval shown in brackets.

<sup>b</sup>From young (15–22 years) patients on peritoneal dialysis. Metabolized by 23-, 24-, and 26-hydroxylases and also excreted into bile as its glucuronide.

<sup>c</sup>CL/F, \(V_{\text{ss}}/<F\), and \(t_{\text{1/2}}\) reported. Following a single 4-mg oral dose (low) given to patients with chronic myelocytic leukemia or a single 1-mg/kg oral dose (high) given as ablative therapy to patients undergoing bone marrow transplantation.

<sup>e</sup>Child: IP: 2–3<sup>d</sup> IP: −90 pg/mL<sup>d</sup> PO: −61

<sup)f</sup>Data from young (15–22 years) patients on peritoneal dialysis. Metabolized by 23-, 24-, and 26-hydroxylases and also excreted into bile as its glucuronide. Calcitriol \(1,25\)-dihydroxyvitamin D<sub>3</sub> is 5–8 h in healthy adult subjects. Oral dose \(t_{\text{1/2}}\) is 27 ± 12 h, children 2–16 years. Following a single 60-ng/kg IV, intraperitoneal (IP) dialysate, or PO dose. Baseline plasma levels were <10 pg/mL.

<sup>g</sup>Canagliflozin renal clearance/total intravenous clearance. Cleared from blood primarily by UGT1A9- and 284-dependend metabolism. Calculated assuming 70-kg body weight. No patients with chronic myelocytic leukemia or a single 1-mg/kg oral dose (high) given as ablative therapy to patients undergoing bone marrow transplantation.

<sup>h</sup>Canagliflozin renal clearance/total intravenous clearance. Cleared from blood primarily by UGT1A9- and 284-dependend metabolism. Calculated assuming 70-kg body weight. Following an intravenous dose reported; longer values (11–13 h) reported following oral administration. Following oral administration. Mean (range or ± SD) following a 100-mg oral dose given once for 7 days to patients with type 2 diabetes mellitus.

<sup>i</sup>Data from young (15–22 years) patients on peritoneal dialysis. Metabolized by 23-, 24-, and 26-hydroxylases and also excreted into bile as its glucuronide.

<sup>a</sup>Data from healthy male and female subjects receiving cetirizine (Rac) or the active R-enantiomer, levocetirizine (Levo).<sup>b</sup>Based on recovery of unchanged drug in urine. CL/F, V/F reported for oral dose. CL/F reduced, hepatocellular and cholestatic liver diseases. CL/F reduced, moderate-to-severe renal impairment. CL/F increased, ages 1–5 years. Following a single 10-mg oral dose of Rac or 5 mg of Levo.

Chloroquine<sup>a</sup>

| –80 | 52–58<sup>a</sup> | S: 66.6 ± 3.3<sup>a</sup> | R: 42.7 ± 2.1 | 3.7–13<sup>b</sup> | 132–261<sup>b</sup> | 10–24 days<sup>b,d</sup> | IV: 837 ± 248 ng/mL<sup>c</sup> |
| IM: 0.25<sup>c</sup> | PO: 3.6 ± 2.0<sup>c</sup> | PO: 76 ± 14 ng/mL<sup>c</sup> |

<sup>a</sup>Active metabolite, desethylchloroquine, accounts for 20% ± 3% of urinary excretion; <i>t</i><sub>1/2</sub> = 15 ± 6 days. Racemic mixture; kinetic parameters for the two isomers are slightly different, CL/F = 136 mL/min and 237 mL/min and V/F = 3410 L and 4830 L for the R-isomer and 5-isomer, respectively. <sup>b</sup>Range of mean values from different studies (intravenous administration). <sup>c</sup>Concentrates in red blood cells. Blood-to-plasma concentration ratio for racemate = 9. <sup>d</sup>A longer <i>t</i><sub>1/2</sub> (41 ± 14 days) has been reported with extended blood sampling. Following a single 300-mg IV dose (24-min infusion) of chloroquine HCl or a single 300-mg IM or oral dose of chloroquine phosphate given to healthy adults. Effective concentrations against *Plasmodium vivax* are 15 ng/mL and 30 ng/mL, respectively. Diplopia and dizziness can occur > 250 ng/mL.

Chlorpromazine<sup>a</sup>

| 32 ± 19<sup>b</sup> | <1 | 95–98 | 8.6 ± 2.9<sup>b</sup> | 21 ± 9<sup>b</sup> | 30 ± 7<sup>b</sup> | 1–4<sup>d</sup> | 25–150 ng/mL<sup>c</sup> |
| Aged | Child |

<sup>a</sup>Active metabolites, 7-hydroxychlorpromazine (<i>t</i><sub>1/2</sub> = 25 ± 15 h) and possibly chlorpromazine N-oxide, yield AUCs comparable to the parent drug (single doses). <sup>b</sup>After a single dose. Bioavailability may decrease to ~ 20% with repeated dosing. CL/F, V/F, and terminal <i>t</i><sub>1/2</sub> following intramuscular administration. <sup>d</sup>Following a 100-mg oral dose given twice a day for 33 days to adult patients. Neurotoxicity (tremors and convulsions) occurs at concentrations of 750–1000 mg/mL.

Chlorthalidone

| 64 ± 10 | 65 ± 9<sup>a</sup> | 75 ± 1 | 0.04 ± 0.01 | 0.14 ± 0.07 | 47 ± 22<sup>a</sup> | 13.8 ± 6.3<sup>c</sup> | 3.7 ± 0.9 μg/mL<sup>c</sup> |
|         | Aged | Child |

<sup>a</sup>Value is for 50- and 100-mg doses; renal CL is decreased at an oral dose of 200 mg, and there is a concomitant decrease in the percentage excreted unchanged. <sup>c</sup>Chlorthalidone is sequestered in erythrocytes; <i>t</i><sub>1/2</sub> is longer if blood, rather than plasma, is analyzed. Parameters reported based on blood concentrations. Following a single 50-mg oral dose (tablet) given to healthy male adults.

Cidofovir<sup>a</sup>

| SC: 98 ± 10 | 70.1 ± 21.4<sup>a</sup> | <6 | 2.1 ± 0.6<sup>a</sup> | 0.36 ± 0.13<sup>a</sup> | 2.3 ± 0.5<sup>a</sup> | — | 19.6 ± 7.2 μg/mL<sup>a</sup> |
| RD | PO: <5 | RD |

<sup>a</sup>Data from patients with HIV infection and positive for cytomegalovirus. Cidofovir is activated intracellularly by phosphorylases. For parenteral use. Parameters reported for a dose given in the presence of probenecid: CL reduced, mild renal impairment (cleared by high-flux hemodialysis). Following a single 5-mg/kg IV infusion given over 1 h, with concomitant oral probenecid and active hydration.

*Cinacalcit is a chiral molecule; the R-enantiomer is more potent than the S-enantiomer and is thought to be responsible for the drug’s pharmacological activity. Cinacalcit is metabolized primarily by CYP3A4, CYP2D6, and CYP1A2. *Unreported, but presumably negligible. Following a single 75-mg oral dose.

*Clopidogrel (Clo) is a produg that is converted to a minor unstable active metabolite (AM) via two sequential cytochrome P450–dependent reactions. The majority of the dose is converted rapidly to an inactive hydrolytic product by esterases. Although multiple P450 isoforms contribute to the formation of AM, blood levels of AM have been associated with the CYP2C19 genotype and phenotype status, with poor metabolizers (PM) exhibiting lower levels, on average, than extensive metabolizers (EM). Formation of AM accounts for ≤ 10% of the administered dose and may be dose dependent due to saturable metabolism. †The absolute bioavailability of Clo is unknown. There is one report of food greatly enhancing the systemic exposure of Clo following oral administration. ‡The reported value may represent disappearance of high levels of metabolite formed during first pass and not the terminal t½, which should be formation limited. •Following a single 300-mg loading dose of Clo.

Clorazepate*  
N: 91 ± 6†  
N: <1  
N: 97.5  
N: 0.17 ± 0.02‡  
N: 1.24 ± 0.09‡  
N: 93 ± 11§  
N: 0.9 ± 0.01±  
N: 356 ± 27 ng/mL∥  

†Clorazepate is essentially a prodrug for nordiazepam (N, desmethyldiazepam). Bioavailability, Tmax and Cmax values for N were derived after oral administration of clorazepate. ‡CL, Vm and t½ values are for intravenous nordiazepam. §Data for N following a 20-mg oral dose of clorazepate.

Clozapine  
55 ± 12  
<1  
>95  
6.1 ± 1.6†  
6.3 ± 1.6†  
5.4 ± 3.5  
12 ± 4  
1.9 ± 0.8§  
546 ± 307 ng/mL∥  

†Clozapine is metabolically cleared, with a major role by CYP1A2 and some minor contributions by CYP3A4, CYP2C19, and CYP2D6. ‡Following titration up to a 150-mg oral dose (tablet) given twice daily for 7 days to adult chronic schizophrenics.

Codeine*  
50 ± 7#  
Negligible  
7  
11 ± 2ε  
2.6 ± 0.3ε  
2.9 ± 0.7  
C: 1.0 ± 0.5ε  
C: 149 ± 60 ng/mL‡  
M: 1.0 ± 0.4ε  
M: 3.8 ± 2.4 ng/mL‡  

*Codeine is metabolized by CYP2D6 (polymorphic) to morphine. Analgesic effect is thought to be due largely to derived morphine. †Oral/intramuscular bioavailability reported. ‡CL/F and Vm/F reported. §Data for codeine (C) and morphine (M) following a 60-mg oral codeine dose given three times daily for seven doses to healthy male adults.

Colchicine  
37 ± 12α  
25–65  
39 ± 5  
1.8 ± 0.4α  
5.3 ± 1.2α  
58 ± 11  
1.0 ± 0.6α  
6.5 ± 1 ng/mLα  

*Increased bioavailability after multiple doses has been reported. †Colchicine is a substrate of P-glycoprotein, which may contribute to its renal and biliary excretion and enterohepatic recirculation. Colchicine is also metabolized by CYP3A4. ‡Colchicine displays multicompartment kinetics with an initial central distribution volume of 0.26 L/kg. §Reported after administration of a single 1-mg tablet.

**Cyclosporine**

SI: 1101 ± 570 ng/mL³

**Cytarabine**

*Cytarabine is rapidly metabolized by deamination to non-toxic uridine arabinoside. Liposome formulation of cytarabine given intrathecally. Cerbrospinal fluid t₁/₂ = 100–203 h for liposome formulation (compared to 3.4 h for intrathecal dose of free drug). t₁/₂ following a single 200-mg/m² IV bolus (IV, B) dose or steady-state plasma concentration following a 112-mg/m²/d constant-rate IV infusion (IV, I) given to patients with leukemia, malignant melanoma, or solid tumors. References: Ho DH, et al. Clinical pharmacology of 1-β-D-arabinofuranosylcytosine. Clin Pharmacol Ther, 1971, 2:285–295. Drugs@FDA: FDA Approved Drug Products (http://www.accessdata.fda.gov/scripts/cder/daf/d/). Dabigatrin (Pradaxa).*

**Dabigatran**

**Dapagliflozin**

*Mean (CV%) reported; high fat meal alters the absorption profile but not the AUC. Calculated as the ratio of dapagliflozin renal clearance/total intravenous clearance. Cleared from blood primarily by UGT1A9-dependent metabolism. Mean (CV% or ± SD) calculated assuming 70-kg body weight. Mean (range or CV%) reported for a 5-mg dose given daily for 7 days. Clearance declines as a function of the severity of renal disease by an unknown mechanism, as the fraction of dapagliflozin excreted unchanged is 3%.

*LANOXIN tablets, digoxin solutions, elixirs, and capsules are absorbed more completely. 1% of the dose is excreted into bile and into feces following intravenous administration. Intestinal and renal excretion of digoxin is mediated by P-glycoprotein and other digoxin-specific transporters. Following an oral dose of 0.31 ± 0.19 mg/d in patients with congestive heart failure who exhibited no signs of digitalis toxicity.

| Diltiazem*              |                        |                     |                       |                  |                  |              |                  |
|                        | 38 ± 11                | <4                  | 78 ± 3                | 11.8 ± 2.2       | 3.3 ± 1.2        | 4.4 ± 1.3    | 4.0 ± 0.4       | 151 ± 46 ng/mL  |
|                        |                        | ↓ RD                |                       | ↓ RD             |                 |              |                  |

*Active metabolites, desacetyldiltiazem (t 1/2 = 9 ± 2 h) and N-desmethydiltiazem (t 1/2 = 7.5 ± 1 h). Formation of desmethyldiltiazem (major pathway of CL) catalyzed primarily by CYP3A. More than a 2-fold decrease with multiple dosing. t 1/2 for oral dose is 5–6 h; does not change with multiple dosing. Following a single 120-mg oral dose to healthy adults.

| Docetaxel*              |                        |                     |                       |                  |                  |              |                  |

|                        |                        | ↑ Aged              |                       |                 |              |              |                  |

*Data from young, healthy male and female subjects. No significant gender differences. Absolute bioavailability is unknown. A fraction bound value of 96% also has been reported. Metabolically cleared by CYP2D6, CYP3A4, and UGT. CL/F, V/F, and t 1/2 reported for oral dose. CL/F reduced slightly (~20%), alcoholic cirrhosis. Following a 5-mg oral dose given once daily to steady state.

| Dolutegravir             |                        |                     |                       |                  |                  |              |                  |
|                        | 98.9                   | 0.27 (45)          | 0.33 (45)            | 14.4 (19)        | 2–3             | 4.15 (29)   | µg/mL           |
|                        |                        | ↓ HIV-1 (LD)       |                       |                 |              |              |                  |

*The absolute oral bioavailability is not known. Cleared from blood predominantly by UGT1A1-dependant metabolism. CL/F and V/F calculated assuming 70-kg body weight; mean (CV%) reported for single oral dose to healthy volunteers. t 1/2 of 11–12 h reported for patients with HIV-1 infection. Mean plasma concentration (CV%) in HIV-1 infected patients receiving 50-mg dolutegravir, twice a day, to steady state.

| Dovastorsin*             |                        |                     |                       |                  |                  |              |                  |
|                        | Y: 65 ± 14             | 5                   | 98                    | 1.26 ± 0.27      | 1.0 ± 0.1       | 20.5 ± 6.1   | 3.9 ± 1.2       | 67 ± 19 ng/mL   |
| E: 68 ± 16              | E: 2.25 ± 1.42         | E: 1.7 ± 1.0       | XL: 19 ± 4           | XL: 9 ± 5        | XL: 28 ± 12 ng/mL |
| XL: F 0.25             | = 59 ± 12             |                     |                       |                 |              |              |                  |

*Where indicated, data for young (Y) and elderly (E) normotensive adults are reported. Also reported are data for a gastrointestinal sustained-release device (GITs), Cardura XL (extended release), oral bioavailability relative to standard formulation (F ss). Cleared primarily by cytochrome P450-dependent metabolism. Study in patients with mild-to-moderate liver impairment. AUC increased 43% (CV%) for single oral dose to healthy volunteers. Following an 8-mg dose of standard formulation or GITs, once daily, to steady state in young and elderly normotensive volunteers.

<tr>
<td>Dronabinol is a synthetic delta-9-tetrahydrocannabinol (delta-9-THC) that is also the active component of cannabis. Dronabinol is extensively metabolized and undergoes extensive first-pass metabolism. It has an active metabolite, 11-OH-delta-9-THC, which is present at about equal concentrations in plasma as THC. Biliary excretion of dronabinol metabolites appears to be a major route of elimination. Only 21% ± 3% of total radioactivity after intravenous dose is recovered in urine, with &gt; 50% recovered in feces. Pulmonary administration of delta-9-THC has a bioavailability of 18%–29%. Bioavailability as high as 20% after oral administration has been reported. Dronabinol elimination is characterized by multicompartment kinetics, with distribution τ&lt;sub&gt;1&lt;/sub&gt;,&lt;sub&gt;d&lt;/sub&gt; of 4 h and terminal τ&lt;sub&gt;1&lt;/sub&gt;,&lt;sub&gt;τ&lt;/sub&gt; of 25–36 h. Following a single oral dose of 5-mg gelatin capsule. Median and range reported for T&lt;sub&gt;1/2&lt;/sub&gt; reported. Following a 0.5-mg dose given once daily to steady state (24 weeks).</td>

*Systemic exposure increased 20%–30% with high-fat meal. †Data from 50-μg/kg IV dose reported; lack of dose proportionality for oral AUC between 20- and 40- or 80-mg doses. ‡Cleared primarily by CYP3A-dependent metabolism. #Study in patients with mild-to-moderate hepatic impairment. †Following single 20–80-mg oral doses; MF: migraine-free period; M: during a migraine attack. Range of mean values from different studies following a single 30-mg oral dose.

| **Enalapril**             |                       |                     |                       |                   |                  |               |                   |
| SC: 92                    | —                     | —                   | 0.3 ± 0.1             | 0.12 ± 0.04       | 3.0 ± 1.3       | 30            | 41 ± 45 ng/mL    |
| ↓ LD                      | ↑ LD                  | ↑ RD, Aged, Neo     |                       |                  |
| ↑ Child                   |                       |                     |                       |                  |

*Hydrolyzed by esterases to the active metabolite, enalaprilic acid (enalaprilat); except when noted, pharmacokinetic values and disease comparisons are for enalaprilat following oral enalapril administration. †For intravenous enalapril. CL/F and Vₘ/F after multiple oral doses of enalapril. Values after single intravenous dose of enalapril are misleading because binding to ACE leads to a prolonged t₁/₂, which does not represent a significant fraction of the CL on multiple dosing. ‡Estimated from the approach to steady state during multiple dosing. ††Mean values for enalaprilat following a 10-mg enalapril oral dose given daily for 8 days to healthy young adults. The Fₚₚ for ACE inhibition is 5–20 ng/mL enalaprilat.

| **Enoxaparin**            |                       |                     |                       |                   |                  |               |                   |
| —                         | 36–60                 | 2.4                 | 0.6–1.3               | 4–6               | 1.8 ± 0.7       | 0.3 ± 0.3 μg/mL |
| ↑ LD                      |                       |                     |                       |                  |

*Enoxaparin consists of low-molecular-weight heparin fragments of varying lengths. †34% is recovered in urine when administered as 55-Tc labeled enoxaparin, 8%–20% anti-factor Xa activity: E: CL/F and Vₘ/F for subcutaneous dose measured by functional assay for anti-factor Xa activity. ‡Measured by functional assay of anti-factor Xa activity. Using anti-IIa activity or displacement binding assay gives a t₁/₂ of ~1.2 h. ††Following a single 40-mg SC dose to healthy adult subjects. High-affinity antithrombin III molecules: ACLM, above-critical-length molecules (anti-factor Xa and IIa activity), BCLM, below-critical-length molecules (anti-factor Xa activity).

| **Eplerenone**            |                       |                     |                       |                   |                  |               |                   |
| —                         | 7 h                   | 33–60               | 2.4                   | 0.6–1.3           | 4–6             | 1.8 ± 0.7     | 0.3 ± 0.3 μg/mL |
| ↑ LD                      |                       |                     |                       |                  |

*Eplerenone is converted (reversibly) to an inactive ring-open hydroxy acid. Both eplerenone (E) and the hydroxy acid (EA) circulate in plasma; concentrations of E are much higher than EA. Irreversible metabolism is catalyzed predominantly by CYP3A4. Data for E in healthy male and female volunteers reported; no significant gender differences. †Recoverd as E and EA following an oral dose. ‡Protein binding is concentration dependent over the therapeutic range; lower at the highest concentration. CL/F and Vₘ/F reported. †Following a 50-mg oral dose given once daily for 7 days.

| **Erlotinib**             |                       |                     |                       |                   |                  |               |                   |
| 59 (55–66)               | —                     | 93 (92–95)          | 1.0 ± 0.4             | 1.2 ± 0.25       | 13               | 2–4           | 1.1–1.7 μg/mL    |
| ↑ Food                   |                       |                     |                       |                  |

*Bioavailability increases to ~100% when taken with a meal, not recommended because food effect is highly variable. †Likely to be low based on reported bioavailability and low recovery of unchanged drug (~2%) after an oral dose. ‡Erlotinib is cleared primarily by CYP3A4 and CYP1A2-dependent metabolism. ††Calculated from a 25-mg IV dose assuming a 70-kg body weight. Systemic exposure reduced by half compared to nonsmokers. †Following a single 150-mg SC dose to 16 patients; shorter t₁/₂ of 36 h was reported for a single 25-mg IV dose. †Following 150-mg oral dose given once daily to steady state.

4 Value for enteric-coated erythromycin base. 5 Decreased concentrations in pregnancy possibly due to decreased bioavailability (or increased CL). 6 Erythromycin base.
7 Erythromycin is a CYP3A substrate, N-demethylation. It is also transported by P-glycoprotein, which may contribute to biliary excretion of parent drug and metabolites. 8 Range of mean values from studies following a 250 mg oral enteric-coated free base in a capsule (B) given four times daily for 5–12 doses or a 250 mg film-coated tablet or capsule of erythromycin stearate (S) given four times daily for 5–12 doses.

Escitalopram, Citalopram

| Es: 8 | Es: 56 | Es: 8.8 ± 3.2 | Es: 15.4 ± 2.4 | Es: 22 ± 6 | — | Es: 21 ± 4 ng/mL |
|——|——|——|——|——|——|——|
| Rac: 80 ± 13 | Rac: 10.5 ± 1.4 | Rac: 4.3 ± 1.2 | Rac: 12.3 ± 2.3 | Rac: 33 ± 4 | Rac: 45 | Rac: 50 ± 9 ng/mL |
| ↓ Aged, LD | ↑ Aged, LD, RD |

*Escitalopram is the active S-enantiomer of racemic citalopram. Pharmacokinetic data after dosing of escitalopram (Es) and citalopram racemate (Rac) are reported. No significant gender differences. Citalopram is metabolized by CYP2C19 (polymorphic) and CYP3A4 to desmethylcitalopram. 1 Data from CYP2C19 extensive metabolizers. CYP2C19 poor metabolizers exhibit a lower (~44%) CL/F and longer t1/2 than extensive metabolizers. 2 CL/F and V/F for Es reported. 3 Following a single 40-mg (Rac) or 20-mg (Es) oral dose.

Esomeprazole, Omeprazole

| Es: 89 (81–98) | Es: Rac: <1 | Es/Rac: 95–97 | Es: 4.1 (3.3–5.0) | Es: 0.25 (0.23–0.27) | Es: 0.9 (0.7–1.0) | Es: 1.5 (1.3–1.7) | Es: 4.5 (3.8–5.7) μM |
|——|——|——|——|——|——|——|——|
| Rac: 53 ± 29 | Rac: 7.5 ± 2.7 | Rac: 0.34 ± 0.09 | Rac: EM: ~1 | Rac: PM: ~1.4 μM |
| ↓ LD | ↑ LD | — | — | — | — | — | — |

*Esomeprazole is the S-enantiomer of omeprazole. Both esomeprazole (Es) and racemic omeprazole (Rac) are available. Data for both formulations are reported. 1 Bioavailability determined after multiple dosing. Lower Es values 44% (54%–75%) reported for single dose. 2 The metabolic CL of the Es is lower than that of the S-enantiomer. Both Es and Rac are metabolized by CYP2C19 (polymorphic) and CYP3A4. CL of Es and Rac is decreased and t1/2 increased in CYP2C19 poor metabolizers. 3 Following a single 40-mg IV dose. CL of Es decreases and t1/2 of Es increases with multiple dosing. 4 Reduced CL and increased t1/2 in patients with severe (Childs-Pugh class C) hepatic impairment. 5 Following a 40-mg oral dose of Es given once daily for 5 days to healthy subjects of unspecified CYP2C19 phenotype. 6 Following a 20-mg oral dose of Rac given twice daily for 4 days to healthy subjects phenotyped as CYP2C19 extensive metabolizers (EM) and poor metabolizers (PM).

Eszopiclone, Zopiclone

| — | Es: <10 | Es: 52–59 | — | — | Es: 7.2 ± 1.3 | Es: 1 (0.4–2.1) | Es: 39.8 ± 8.6 ng/mL |
|——|——|——|——|——|——|——|——|
| — | ↑ LD |

*Eszopiclone is the (S)-isomer of zopiclone. Pharmacokinetic data after dosing of eszopiclone (Es) is shown. Es is metabolized extensively by CYP3A4 and CYP2E1. 1 CL/F following a 15-mg oral dose of zopiclone is 2.7 mL/min/kg for Es and 4.4 mL/min/kg for racemic zopiclone. 2 CL/F following a 15-mg oral dose of racemic zopiclone is 1.4 L/kg for eszopiclone and 2.2 L/kg for racemic zopiclone. 3 Patients with severe hepatic impairment. 4 Following 3-mg Es given once daily to steady state.

Ethambutol

| 77 ± 8 | 79 ± 3 | — | — | 8.6 ± 0.8 | 1.6 ± 0.2 | 3.1 ± 0.4 | 2–4 μg/mL |
|——|——|——|——|——|——|——|——|
| ↑ RD |

*Following a single 800-mg oral dose to healthy subjects. Concentrations > 10 μg/mL can adversely affect vision. No accumulation with once-a-day dosing in patients with normal renal function.

*Metabolically cleared primarily by CYP3A to norfentanyl and hydroxy metabolites. Following a 5-mg transdermal (TD) dose administered at 50 μg/h through a Duragesic system or a single 400-μg transmucosal (TM) dose. Postoperative and intraoperative analgesia occurs at plasma concentrations of 1 ng/mL and 3 ng/mL, respectively. Respiratory depression occurs at > 0.7 ng/mL.

| ↓ RD, LD                  | ↑ LD                   | ↑ RD, LD            |                       |                 |                 |               |                   |
| ↑ Child                   | ↓ Child                |                     |                       |                 |                 |               |                   |

*Racemic mixture; enantiomers exert similar electrophysiological effects. Metabolized by CYP2D6 (polymorphic); except for a shortened elimination t1/2 and nonlinear kinetics in extensive metabolizers, CYP2D6 phenotype had no significant influence on flecainide pharmacokinetics or pharmacodynamics. V1/F reported. Following a 100-mg oral dose given twice daily for 5 days in healthy adults. Similar levels for CYP2D6 extensive and poor metabolizers.

| **Fluconazole**            |                        |                     |                       |                 |                 |               |                   |
| >90                       | 75 ± 9                 | 11 ± 1              | 0.27 ± 0.07           | 0.60 ± 0.11     | 32 ± 5         | 1.7–4.3°    | 10.6 ± 0.4 μg/mL |

*Following a 200-mg oral dose given twice a day for 4 days to healthy adults.

| **Fludarabine**            |                        |                     |                       |                 |                 |               |                   |
| —                         | 24 ± 3                 | —                   | 3.7 ± 1.5             | 2.4 ± 0.6       | 10–30          | —           | 0.57 μg/mL       |
| ↓ RD                      |                        |                     |                       |                 |                 |               |                   |

*Data from adult male and female cancer patients following intravenous administration. Fludarabine is rapidly dephosphorylated to 2 fluoro-arabinoside A (F-ar-a-A), transported into cells, and phosphorylated to the active triphosphate metabolite. Pharmacokinetics of F-ar-A are reported. Following a single 25-mg/m² IV dose of fludarabine (30-min infusion), no accumulation after five daily doses.

| **5-Fluorouracil (5FU)**   |                        |                     |                       |                 |                 |               |                   |
| 28 (0–80)°                | <10                    | 8–12                | 16 ± 7                | 0.25 ± 0.12     | 11 ± 4 min°    | —           | 11.2 μM°         |

*Higher F with rapid absorption and lower F with slower absorption due to a saturable first-pass effect. A much longer (~20 h) terminal t1/2 has been reported, representing a slow redistribution of drug from tissues. Steady-state concentration following a continuous intravenous infusion of 300–500 mg/m²/d to cancer patients.

<sup>a</sup>Active metabolite, norfluoxetine; t<sub>1/2</sub> of norfluoxetine is 6.4 ± 2.5 days (12 ± 2 days in cirrhosis). Absolute bioavailability is unknown, but ≥ 80% of the dose is absorbed. <sup>b</sup>Reduced CL with repetitive dosing (~2.6 mL/min/kg) and with increasing dose between 40 and 80 mg. <sup>c</sup>CL/F reported; fluoxetine is a CYP2D6 and CYP2C19 substrate and inhibitor but steady state elimination is not dependent on these enzymes because of autoinhibition. <sup>d</sup>Longer t<sub>1/2</sub> with repetitive dosing and with increasing doses. <sup>e</sup>Range of data for fluoxetine (F) and norfluoxetine (NF) following a 60-mg oral dose given once daily for 1 week. NF continues to accumulate for several weeks. 

| **Fluphenazine**<sup>b</sup> | PO: 2.7 (1.7–4.5)<sup>b</sup> | Negligible          | —        | 10 ± 7<sup>c</sup> | 11 ± 10 | IV: 12 ± 4<sup>d</sup> | IR: 2.8 ± 2.1<sup>d</sup> | IR: 2.3 ± 2.1 ng/mL<sup>e</sup> |

</tbody>
</table>

<sup>a</sup>Undergoes reversible metabolism to a less active reduced haloperidol. <sup>b</sup>Represents net CL of parent drug; reduced haloperidol CL = 10 ± 5 mL·min⁻¹·kg⁻¹ and t<sub>1/2</sub> = 67 ± 51 h. Slow conversion from reduced haloperidol to parent compound probably responsible for prolonged terminal t<sub>1/2</sub> (70 h) for haloperidol observed with 7-day sampling. Following a single 20-mg oral or 10-mg IM dose. Effective concentrations are 4-20 ng/mL.

| **Heparin** | | | | | | | |
| —           | | | | | | | |
| Negligible  | Extensive            | 1/(0.65 + 0.008D)+ 0.1<sup*c</sup> | 0.058 ± 0.11<sup>c</sup> | (26 + 0.323D) ± | 3<sup>c</sup> | 70 ± 39 ng/mL<sup>c</sup> |

<sup>c</sup>Dose (D) is in international units per kilogram. CL<sub>rd</sub> and t<sub>1/2</sub> are dose dependent, perhaps due to saturable metabolism with end-product inhibition. V<sub>ss</sub> reported: *Mean of above critical length molecules following a single 5000-UU dose (unfractionated) given by SC injection.*

| **Hydrochlorothiazide** | | | | | | | |
| 71 ± 15              | >95                  | 58 ± 17              | 4.9 ± 1.1<sup>c</sup> | 0.83 ± 0.31<sup>c</sup> | 2.5 ± 0.2<sup>c</sup> | SD: 1.9 ± 0.5<sup>c</sup> | SD: 75 ± 17 ng/mL<sup>c</sup> |

<sup>c</sup>Renal CL reported, which should approximate total plasma CL. V<sub>ss</sub> <sup>c</sup>calculated from individual values of renal CL, terminal t<sub>1/2</sub> and fraction of drug excreted unchanged, 70-kg body weight assumed. Longer terminal t<sub>1/2</sub> of 8 ± 2.8 h has been reported with a corresponding increase in V<sub>ss</sub> to 2.8 L/kg. Following a single (SD) or multiple (MD) 12.5-mg oral dose, hydrochlorothiazide was given daily for 3 days to healthy adults.

| **Hydrocodone**<sup>a</sup> | | | | | | | |
| —           | | | | | | | |
| EM: 10.2 ± 1.8 | — | EM: 11.1 ± 3.57<sup>b</sup> | — | EM: 4.24 ± 0.99<sup>b</sup> | EM: 0.72 ± 0.46<sup>b</sup> | EM: 30 ± 9.4 ng/mL<sup>c</sup> |

<sup>a</sup>Data from healthy male and female subjects. The metabolism of hydrocodone to hydromorphone (more active) is catalyzed by CYP2D6. Subjects were phenotyped as extensive (EM) or poor metabolizers (PM). CL<sub>rd</sub> and t<sub>1/2</sub> reported: Following a single 2-mg IV (bolus, sample at 3 min) or 4-mg oral dose. Maximal hydrocholorothiazide concentrations are higher in EM than in PM (5.2 vs. 1.0 ng/mL).

| **Hydromorphone**<sup>a</sup> | | | | | | | |
| PO: 42 ± 23 | 6 | 7.1 | 14.6 ± 7.6 | 2.90 ± 1.31<sup>b</sup> | 2.4 ± 0.6 | IV: —<sup>c</sup> | IV: 242 ng/mL<sup>c</sup> |

<sup>a</sup>Data from healthy male subjects. Extensively metabolized. The principal metabolite, 3-glucuronide, accumulates to much higher (27-fold) levels than the parent drug and may contribute to some side effects (not antinociceptive). V<sub>ss</sub> reported: Following a single 2-mg IV (bolus, sample at 3 min) or 4-mg oral dose. Maximal hydrochlorothiazide concentrations are higher in EM than in PM (5.2 vs. 1.0 ng/mL).

| **Hydroxychloroquine**<sup>a</sup> | | | | | | | |
| 79 ± 12 | 27 | 45 ± 3 | 11.9 ± 5.4<sup>a</sup> | 525 ± 158 | 1056 (624–1512) | 3.2 (2–4.5) | 46 (34–79) ng/mL<sup>a</sup> |

<sup>a</sup>Hydroxychloroquine is marketed as a racemic mixture of R- and S-hydroxychloroquine. Data for the racemic mixture is reported. Plasma clearance is reported. Hydroxychloroquine accumulates in red blood cells with an average blood-to-plasma ratio of 7:2. Blood clearance of hydroxychloroquine is 1.3 mL/min/kg. Following oral administration of a single 155-mg tablet.

Hydroxyurea is metabolized to an active metabolite, cetirizine. Plasma concentrations of cetirizine exceed those of the parent drug; its t₁/₂ is similar to that of hydroxyurea when formed from parent drug. Hydroxyurea data for adults (A) and children (C) are reported. *CL/F, V/F, and t₁/₂ after oral dose reported. t₁/₂ increases with increasing age (1–15 years). Following a single 0.7-mg/kg oral dose given to healthy adults and children.

| Ibandronate              |                       |                     |                      |                  |                 |               |                  |

</table>

<sup>a</sup>Imatinib is metabolically cleared primarily by CYP3A4. Following a 400 mg oral dose given once daily to steady state.

<sup>b</sup>Formulated as a 1:1 (mg/mg) mixture for parenteral administration; cilastatin inhibits the metabolism of imipenem by the kidney, increasing concentrations of imipenem in the urine; cilastatin does not change imipenem plasma concentrations appreciably. Plasma C<sub>max</sub> of imipenem following a single 1-g IV infusion over 30 min or 750 mg IM injection.

<sup>c</sup>Undergoes significant enterohepatic recycling (~50% after an intravenous dose). Following a single 50-mg oral dose given after a standard breakfast. Effective at concentrations of 0.3–3 μg/mL and toxic at >5 μg/mL.

<sup>d</sup>Values for recombinant interferon alfa-2a (I) and its 40-kDa pegylated form (PI<sub>40kDa</sub>) and the 12-kDa pegylated form of interferon alfa-2b (PI<sub>12kDa</sub>) are reported. I undergoes renal filtration, tubular reabsorption, and proteolytic degradation within tubular epithelial cells. Renal elimination of PI form is much less significant than that of I, although not negligible. CL values in four patients with leukemia were more than halved (1.1 ± 0.3 mL/min/kg), while V<sub>ser</sub> increased more than 20-fold (9.5 ± 3.5 L/kg) and terminal t<sub>1/2</sub> changed only minimally (7.3 ± 2.4 h). A terminal t<sub>1/2</sub> of 5.1 ± 1.6 h accounts for 23% of the CL of I. Following a single 36 × 10<sup>6</sup> units SC dose of I. Following 4 weeks of multiple SC dosing of 1 μg of PI<sub>40kDa</sub>. Following 48 weekly SC doses of 180 μg/kg of PI<sub>12kDa</sub>. Refer to: Glue P, et al. Pegylated interferon-2b pharmacokinetics, pharmacodynamics, safety, and preliminary efficacy data. Hepatitis C Intervention Therapy Group. Clin Pharmacol Ther, 2000, 68:556–567. Harris J, et al. Pegylation: a novel process for modifying pharmacokinetics. Clin Pharmacokinet, 2001, 40:39–51. Pharm Res, 2000, p. 2654. Wills RJ. Clinical pharmacokinetics of interferons. Clin Pharmacokinet, 1990, 19:390–399.

<sup>e</sup>Undergoes renal filtration, tubular reabsorption, and renal catabolism, but hepatic uptake and catabolism are thought to dominate systemic CL. Concentration at 5 min following a single 90 × 10<sup>6</sup> IU IV dose or following a single 90 × 10<sup>6</sup> IU SC dose of recombinant interferon beta-1b.

*Active metabolite of isosorbide dinitrate. Following a 20-μg oral dose given by asymmetric dosing (0 and 7 h) for 4 days. Reference: Abshagen UW. Pharmacokinetics of isosorbide mononitrate. Am J Cardiol, 1992, 70:64G–66G.

*Isotretinoin (I) is eliminated through metabolic oxidations catalyzed by multiple CYPs (2C8, 2C9, 3A4, and 2B6). The 4-oxo-isotretinoin metabolite (4-oxo) is active and found at higher concentrations than parent drug at steady state. Bioavailability when taken with food is reported. CL/F and V/F reported. 4-oxo has an apparent mean t½ of 29 ± 6 h.

*Values for I and 4-oxo following a 30-μg oral dose given once daily to steady state.

*Metabolized predominantly by CYP3A4 to an active metabolite, hydroxyitraconazole, and other sequential metabolites. Relative to oral dosing with food: Blood CL is 9.4 mL/ min/kg. CL is concentration dependent; the value given is nonsaturable range. K = 330 ± 200 ng/mL, V = 2 ± 0.8 pg · mL⁻¹ · min⁻¹ · kg⁻¹. Apparent CL/F at steady state reported to be 5.4 mL · min⁻¹ · kg⁻¹.

*Following a single 150-μg/kg oral dose (tablet).

*Fifteen isomers are known, with a total of over 100 optical isomers. CYP3A is the main enzyme responsible for its metabolism.

*Following a 200-mg oral dose given daily for 4 days to adults.

*The clinical formulation of labetalol consists of equal proportions of 4 optical isomers. Bioavailability correlates with age and increases with age. Bioavailability appears to increase with multiple dosing. Labetalol is mainly cleared by glucuronidation. Labetalol displays multicompartment distribution kinetics with an initial t½ of 1.4 h. Following a 200-mg dose of labetalol every 12 h for 5 doses.

*Following a single 100-mg oral dose (tablet).

*Data from male and female patients treated for onchocerciasis. Metabolized by hepatic enzymes and excreted into bile: CL/F, V/F, and t½ reported for oral dose. Terminal t½ reported. Following a single 150-µg/kg oral dose (tablet).

*Follows multicompartment kinetics. Does not appear to be concentration dependent.

*Data from healthy male subjects. No significant gender differences. CL/F decreased, moderate and severe renal impairment. Weight-normalized CL/F increased, children < 12 years of age. Following a single 100-mg oral dose (tablet).

*Following a 200-mg oral dose given daily for 4 days to adults.

*Following a 200-mg oral dose given daily for 4 days to adults.

*Following a 200-mg oral dose given daily for 4 days to adults.

*Data from healthy adults and patients with epilepsy. Range of mean values from multiple studies reported. Lamotrigine is eliminated primarily by glucuronidation. The parent-metabolite pair may undergo enterohepatic recycling. CL/F increases slightly with multiple-dose therapy. CL/F increased and t½ decreased in patients receiving enzyme-inducing anticonvulsant drugs. CL/F reduced, moderate-to-severe hepatic impairment. CL/F reduced, severe RD. Following a single 200-μg oral dose to healthy adults.

*Following a single 200-μg oral dose (tablet).

- HDL (DL): 2.0 ± 0.6 ng/mL<sup>e</sup>
- RD, LD

<sup>a</sup>Currently formulated in combination with ritonavir (Kaletra). Ritonavir inhibits the CYP3A-dependent metabolism of lopinavir, enhancing its bioavailability, increasing plasma concentrations (30- to 100-fold), and extending its t<sub>1/2</sub>. Pharmacokinetic data from male and female patients with HIV are reported. Absolute bioavailability is not known; the relative bioavailability increases with a high-fat meal. <sup>b</sup>CL/F and V<sub>area</sub>/F reported; calculated from steady-state AUC data. Following a 400-1000 mg lopinavir/ritonavir oral dose given twice daily in combination with stavudine and lamivudine to steady-state.

### Loratadine<sup>a</sup>

<sup>a</sup>Loratadine (L) is converted to a major active metabolite, desloratadine (DL). Almost all patients achieve higher plasma concentrations of DL than of L. DL (Clarinex) is approved for similar clinical indications as L. DL is eliminated by metabolism to an active metabolite, 3-hydroxydesloratadine (HDL). ~7%–20% of patients were slow metabolizers of DL; ~14% of patients were fast metabolizers of DL. Loratadine is metabolized by CYP2C9 to HDL ( trough concentrations (50- to 100-fold), and extending its t<sub>1/2</sub>. Pharmacokinetic data from male and female patients with HIV are reported. Absolute bioavailability is not known; the relative bioavailability increases with a high-fat meal. <sup>b</sup>CL/F and V<sub>area</sub>/F reported; calculated from steady-state AUC data. Following a 400-1000 mg lopinavir/ritonavir oral dose given twice daily in combination with stavudine and lamivudine to steady-state.

\(^{L}\)Lovastatin is an inactive lactone that is metabolized to the corresponding active β-hydroxy acid. Pharmacokinetic values are based on the sum of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibition activity by the β-hydroxy acid and other less potent metabolites. The lactone (in equilibrium with β-hydroxy acid metabolite) is metabolized by CYP3A. Following an 80-mg oral dose given once daily for 17 days. Peak levels represent total active inhibitors (AI) and total inhibitors (TI) of HMG-CoA reductase.

| Mefloquine* | — | <1 | 98.2 | 0.43 ± 0.14 | 19 ± 6 | 20 ± 4 days | SD: 7–19.6 | SD: 800–1020 ng/mL\(^{L}\) |

| ↑ LD | ↓ Aged, RD | ↓LD, RD, Prem, Neo | ↓ Aged, Prem | ↑ LD, Prem, Neo, Aged, RD | MD: 12 ± 8 | MD: 420 ± 141 ng/mL\(^{L}\) |

* Meperidine undergoes cytochrome P450–dependent -demethylation to normeperidine. The metabolite is not an analgesic but is a potent central nervous system–excitatory agent and is associated with adverse side effects of meperidine. *Meperidine is a weak base (\( pK_{a} = 8.6 \)) and is excreted to a greater extent in the urine at low urinary pH and to a lesser extent at high urinary pH. *Correlates with the concentration of α, -acid glycoprotein. *A longer \( t_{1/2} \) (7 h) also is observed. *Following a continuous 24-mg/h IV infusion or 100-mg IM injection every 4 h to steady state. Postoperative analgesia occurs at 0.4–0.7 μg/mL.

| Mercaptopurine* | 12 ± 7 | 22 ± 12 | 19 | 11 ± 4 | 0.56 ± 0.38 | 0.90 ± 0.37 | IV: 6.9 μM\(^{d}\) |
| ↓ PO (–): 2.4 ± 0.4 | ↓ PO (+): 2.8 ± 0.6 | ↓ PO (-): 0.28 μM | ↓ PO (+): 3.7 ± 0.6 μM |

*Inactive prodrug is metabolized intracellularly to 6-thioguanosine. Pharmacokinetic values for mercaptopurine are reported. *Increases to 60% when first-pass metabolism is inhibited by allopurinol (100 mg three times daily). *Metabolically cleared by xanthine oxidase and thiospurine methyltransferase (polymorphic). Despite inhibition of intrinsic CL by allopurinol, hepatic metabolism is limited by blood flow, and CL is thus little changed by allopurinol. *Following an intravenous infusion of 30 mg/m²/h to steady-state in children with refractory cancers or a single oral dose of 75 mg/m² with (+) or without (–) allopurinol pretreatment.

| Metformin* | 52 ± 5 (40–55) | 99.9 ± 0.5 (79–100) | Negligible | 7.62 ± 0.30 (6.3–10.1) | 1.12 ± 0.08 (0.9–3.94) | 1.74 ± 0.20 (1.5–4.5) | 1.9 ± 0.4 (1.5–3.5) | 1.6 ± 0.2 μg/mL\(^{L}\) |
| ↓ RD, ↑ Aged | ↓ Preg | ↓ RD, ↑ Aged | — | — | — | — | — | (1.0–3.1 μg/mL)\(^{L}\) |

*Data from healthy male and female subjects. No significant gender differences. Shown in parentheses are mean values from different studies. *Clearance of metformin is mediated in part by organic cation transporters (OCTs) in the kidney. *CL/F reduced, mild-to-severe renal impairment. *Following a single 0.5-g oral dose (tablet) and range for a 0.5- to 1.5-g oral dose.

**Methadone**

- Data for racemic mixture. Opioid activity resides with the R-enantiomer. In vivo disposition is stereoselective. N-demethylation is mediated by CYP2A4 and CYP2B6. Inversely correlated with urine pH. 'd'-methadone slightly higher percentage bound. Theoretical values based on studies of single oral doses in patients with chronic pain or at 0.12- to 1.9-mg/kg oral dose once daily for at least 2 months in subjects with opioid dependency. Levels > 100 ng/mL prevent withdrawal symptoms; EC₅₀ for pain relief and sedation in cancer patients is 350 ± 180 ng/mL. 

**Methotrexate**

- Plasma concentrations of the 7-hydroxy metabolite approach those of the parent drug. Metabolite may have both therapeutic and toxic effects. Bioavailability is dose dependent and may be as low as 20% when doses are > 80 mg/m². Intramuscular bioavailability is only slightly higher. Methotrexate clearance is mediated by several transporters, including organic anion transporters (OATs). Exhibits triexponential elimination kinetics. A shorter T₁/₂ (2 h) is seen initially, and a longer (52 h) terminal Tₚₚ has been observed with increased assay sensitivity. Following a 15-mg SC dose given once weekly to steady state in adult patients with inflammatory bowel disease. Initial steady-state concentrations in young (1.5–22 years) leukemia patients receiving a 500-mg/m² loading dose given over 1 h followed by an infusion of 196-mg-m²/h for 5 h. 

**Phenytoin**

- May be decreased to 50%–60% with high doses. Mean at 1 h following a 28-mg IV infusion over 20 min given twice daily for 6 ± 4 days during the perioperative period following kidney transplantation. Mean data following a 24-mg oral dose given twice daily for 3 days in healthy adult male subjects. 

**Methylprednisolone**

- Following a single 20-mg oral dose given to healthy adults (A) or an oral (nasogastric) dose of 0.10–0.15 mg/kg given four times daily to steady state to premature infants (I), 1–7 weeks of age (28–36 weeks, postconceptional). 

**Metoclopramide**

- Following a single 20-mg oral dose given to healthy adults (A) or an oral (nasogastric) dose of 0.10–0.15 mg/kg given four times daily to steady state to premature infants (I), 1–7 weeks of age (28–36 weeks, postconceptional).

**Metoprolol**

| 38 ± 14* | 10 ± 3b | 11 ± 1 | 15 ± 3b | 4.2 ± 0.7 | 3.2 ± 0.2a | EM: −2c | EM: 99 ± 53 ng/mL |
|↓ LD | ↑ Preg | ↑ Fem | ↑ LD, Neo | ↓ Neo, LD |

*Data for racemic mixture reported. Metabolism of less active R(+)-enantiomer (CL/F = 28 mL/min/kg; Vgeo/F = 7.6 L/kg; t1/2 = 2.7 h) is slightly faster than that of more active S(-)-enantiomer (CL/F = 20 mL/min/kg; Vgeo/F = 5.5 L/kg; t1/2 = 3 h). *Metabolically cleared by CYP2D6 (polymorphic). Compared to extensive metabolizers (EM), individuals who are poor metabolizers (PM) have a lower CL/F and a longer t1/2 (7.6 ± 1.5 vs. 2.8 ± 1.2 h) and excrete more unchanged drug in urine (15% ± 7% vs. 3.2% ± 3%) due to reduced hepatic metabolism. *Cp, following a single 100-mg oral dose in CYP2D6 EM and PM patients with hypertension. Plasma concentrations of the more active S-enantiomer are ~35% higher than the R-antipode in CYP2D6 EM. No stereochromical difference was observed in PM subjects. EUC, for decreased heart rate during peak submaximal exercise testing was 16 ± 7 ng/mL, EUC, for decreased systolic blood pressure during exercise testing was 25 ± 18 ng/mL.

**Metronidazole**

| 99 ± 8b | 10 ± 2 | 11 ± 3 | 1.3 ± 0.3 | 0.74 ± 0.10 | 8.5 ± 2.9 | IV: 27 (11–41) μg/mL |
|↓ LD, Neo | ↑ Neo, LD |
|PO: 2.8c | PO: 19.8 μg/mL |
|VA: 11 ± 2 | VA: 1.9±0.2 μg/mL |

*Active dehydroxylated metabolite accumulates in renal failure. *Bioavailability is 67%–82% for rectal suppositories and 53% ± 16% for intravaginal gel. Following a single 100-mg dose of vaginal (VA) cream, a 100-mg IV infusion over 20 min three times daily to steady state or a 100-mg oral dose three times daily to steady state.

**Micafungin**

| — | <1 | 99 | 0.14 ± 0.03a | 0.20 ± 0.03 | 14.6 ± 3.0 | — | 8.8 ± 1.8 μg/mLb |

*Undergoes arylsulfatase-dependent metabolism and biliary excretion. *Following a 100-mg IV infusion administered over 1 h.

**Midazolam**

| 44 ± 17a | <1% | 98 | 6.6 ± 1.8b | 1.1 ± 0.6 | 1.9 ± 0.6 | IV: 113 ± 16 ng/mLc |
|↑ LD | ↓ Aged, RD | ↑ RD | ↑ Obes | ↑ Aged, Obes, LD |
|↓ LD, Neo | ↑ Neo |

*Undergoes extensive first-pass metabolism by intestinal and hepatic CYP3A. Bioavailability appears to be dose dependent; 35%–67% at 15-mg, 28%–36% at 7.5-mg, and 12%–47% at 2-mg oral dose, possibly due to saturable first-pass intestinal metabolism. *Metabolically cleared by CYP3A. *Increased CL due to increased plasma free fraction; unbound CL is unchanged. *Following a single 5-mg IV bolus or 10-mg oral dose.

**Minocycline**

| 95–100 | 11 ± 2 | 76 | 1.0 ± 0.3a | 1.3 ± 0.2b | 16 ± 2 | IV: 3.5 μg/mL |
| — | 85 | 9.12 ± 1.14d | 4.5 ± 1.7 | 16.3 ± 4.64a | 1.5 ± 0.7f | 41.8 ± 7.7 ng/mL |
|PO: 2–4 | PO: 2.3–3.5 μg/mL |

*Cleared primarily by oxidative metabolism in the liver. *Vgeo reported. *Following a single 200-mg IV infusion (1 h) or range of values following a 100-mg oral dose given twice a day to steady state.

**Mirtazapine**

| 50 ± 10 | — | 85 | 9.12 ± 1.14d | 4.5 ± 1.7 | 16.3 ± 4.64a | 1.5 ± 0.7f | 41.8 ± 7.7 ng/mL |
| — | — | — | — | ↑ LD; RD4 |

*Data from healthy adult subjects. Metabolized by CYP2D6 and CYP1A2 (8-hydroxy) and CYP3A (N-desmethyl, N-oxide). *Women of all ages exhibit a lower CL/F and longer t1/2 than men. *CL/F reduced, hepatic impairment. *CL/F reduced, moderate-to-severe renal impairment. *The t1/2 of the (+)-antipode is approximately twice as long as the (-)-antipode; approximately 3-fold higher blood concentrations (+ vs. –) are achieved. *Following a 15-mg oral dose given once daily to steady state.

</table>

*Data from healthy adult subjects. No significant gender differences. *Montelukast is metabolized by CYP3A4 and CYP2C9. **CL/F is reduced by 41%, mild-to-moderate hepatic impairment with cirrhosis. Following a single 10-mg oral dose.

Morphine*  

| PO: 24 ± 12 | 4 ± 5  | 35 ± 2 | 24 ± 10 | 3.3 ± 0.9 | 1.9 ± 0.5 | 0.7 ± 0.3 | 10 ng/mL |
| IM: –100 |  
| ↓ LD | ↓ RD, Prem | ↓ RD | ↑ Neo, Prem | PO-IR: 0.5–1.5b | IM: –70 ng/mLb | PO-SR: 3–8b |

*Mainly cleared by UGT2B7-dependent glucuronidation to morphine-3-glucuronide and to an active metabolite, morphine-6-glucuronide; the latter urinary excretion is 14% ± 7% and t1/2 = 0.9 ± 1.5 h. Steady-state ratio of active metabolite to parent drug after oral dosing = 4.9 ± 3.8. In renal failure, t1/2 increases to 50 ± 37 h, resulting in significant accumulation of active glucuronide metabolite. Following a single 10-mg IV dose (bolus with 5-min blood sample), a 10-mg/70-kg IM, a 10-mg/70 kg immediate-release oral (PO-IR) dose, or a 50-mg sustained release oral dose (PO-SR). Minimum analgesic concentration is 15 ng/mL.

Moxifloxacin*  

| 86 ± 1 | 21.9 ± 3.6 | 39.4 ± 2.4 | 2.27 ± 0.24e | 2.05 ± 1.15 | 15.4 ± 1.2 | 2.0 (0.5–6.0)c | 2.5 ± 1.3 μg/mLc |

*Data from healthy adult male subjects. *Moxifloxacin is metabolically cleared by ST and UGT. **Following a single oral 400-mg dose.

Mycophenolate*  

| MM: –0 | MPA: <1 | MPA: 97.5 | MM: 120–163 | MPA: 3.6–4c | MM: <0.033 | MPA: 1.1–2.2c | MPA: 8–19 μg/mLc |
| MPA: 94 |  
| ↓ RDb | MPA: 2.5 ± 0.4c | MPA: 16.6 ± 5.8 |

*Data from healthy adult male and female subjects and organ transplant patients. No significant gender differences. Mycophenolate mofetil (MPM) is rapidly converted to the active mycophenolic acid (MPA) after intravenous and oral doses. Kinetic parameters refer to MM and MPA after a dose of MM. MPA metabolized by UGT to MPA-glucuronide (MPAG). MPA undergoes enterohepatic recycling; MPAG is excreted into bile and presumably is hydrolyzed by gut flora and reabsorbed as MPA. *Accumulation of MPA and MPAG and increased unbound MPA; severe renal impairment. CL/F and Vc/F reported for MPA. **Range of mean MPA t1/2 and Vc/F from different studies following a 1- to 7.5-g oral dose given twice daily to steady state in renal transplant patients.

Naltrexone*  

| 20 ± 5 | 2 | 21 | 18.3 ± 1.4 | 16.1 ± 5.2 | 10.3 ± 3.3c | 1c | 15–64 ng/mLc |
|  
|  
| ↓ LDc |

*Naltrexone has an active metabolite, 6β-naltrexol, that circulates at greater concentrations than naltrexone and has a 10-fold higher AUC than naltrexone after oral administration of naltrexone. *The oral AUC of naltrexone was significantly increased in patients with liver impairment, whereas the AUC of 6β-naltrexol was not changed. **A t1/2 of 2.7 h after intravenous administration also reported. Following a single 100-mg oral dose.

Naproxen  

| 99c | 5–6 | 99.7 ± 0.1b | 0.13 ± 0.02le | 0.16 ± 0.02c | 14 ± 1 | T-IR: 2–4f | T-IR: 37 μg/mLf |
|  
| 5–6 | 99.7 ± 0.1b | 0.13 ± 0.02le | 0.16 ± 0.02c | 14 ± 1 | T-IR: 2–4f | T-IR: 37 μg/mLf |

*Estimated bioavailability. *Saturable protein binding yields apparent nonlinear elimination kinetics. **No change in total CL, but a significant (50%) decrease in CL of unbound drug, it is thus suggested that dosing rate be reduced. A second study in elderly patients found a decreased CL and increased t1/2 with no change in percentage bound. 

*Metabolically cleared by CYP2C9 (polymorphic) and CYP1A2. **CL/F and Vc/F reported. Following a single 250-mg dose of suspension (S) given orally to pediatric patients or a 250-mg immediate-release tablet (T-IR) or a 500-mg controlled-release tablet (T-IR) given to adults.

(Continued)
Oxalipatin is an organophosphonate complex. Pt is coordinated with diaminocyclohexane (DACH) and an oxalate ligand as a leaving group. Oxalipatin (Ox) undergoes nonenzymatic bioransformation to active derivatives, notably Pt(DACH)Cl₂ (PDTC). Antitumor activity and toxicity are thought to relate to the concentration of oxalipatin and PDTC in plasma ultrafiltrate (i.e., unbound concentration). For intravenous administration only, -54% of the platinum eliminated is recovered in urine. Binding to plasma proteins is irreversible. Concentration of total platinum is much lower; ~2–4 mL/min/kg. The elimination of platinum species in plasma follows a triexponential pattern. The quoted t₁/₂ reflects the t₁/₂ of the first phase, which is the clinically relevant phase. The t₁/₂ for the slower two phases are 17 and 391 h. Steady-state plasma ultrafiltrate concentration of Ox and PDTC after an 85-mg/m² IV infusion over 2 h during cycles 1 and 2.

</table>

Data from healthy female subjects. No significant gender differences. Racemic mixture, anticholinergic activity resides predominantly with R-enantiomer; no stereoselectivity exhibited for anti-spasmudic activity. Oxybutynin undergoes extensive first-pass metabolism to N-desethyl oxybutynin (DEO), an active, anticholinergic metabolite. Metabolized primarily by intestinal and hepatic CYP3A. Racemic oxybutynin kinetic parameters reported. *Data reported for a 1-mg IV dose, assuming a 70-kg body weight. A larger volume (2.8 L/kg) and longer t₁/₂ (5.5 h) reported for a 5-mg IV dose. *Exhibits a longer apparent t₁/₂ following oral dosing due to absorption rate-limited kinetics: immediate-release (IR) t₁/₂, 9 ± 2 h; extended-release (XL) t₁/₂, 14 ± 3 h. The apparent t₁/₂ for DEO was 4.0 ± 1.4 h and 8.3 ± 2.5 h for the IR and XL formulations, respectively. *Following a dose of 5-mg IR given three times daily or 15-mg XL given once daily for 4 days. Peak DEO levels at steady state were 45 and 23 ng/mL for IR and XL, respectively.

### Oxycodone

*Oxycodone is metabolized primarily by CYP3A4/5, with a minor contribution from CYP2D6. Oxymorphone is an active metabolite produced by CYP2D6-mediated O-dealkylation. The circulating concentrations of oxymorphone are too low to contribute significantly to the opioid effects of oxycodone. Data from healthy male and female subjects reported. *Values reported for OXYCONTIN (oxycodone controlled release (CR)) and immediate-release (IR) tablets. *Up to 19% excreted unchanged after an oral dose. *The apparent t₁/₂ for the CR oral formulation is ~5 h; this most likely reflects absorption-limited terminal elimination kinetics. Following 18 mg of OXYCONTIN (CR) given twice daily to steady state or a 5-mg IR tablet given every 6 h to steady state.

*Binding of drug to dialysis filtration devices may lead to overestimation of protein binding fraction (88% suggested). *Metabolized by CYP2C8 and CYP3A, and substrate for P-glycoprotein. *Average accumulation t₁/₂ longer terminal t₁/₂ up to 50 h are reported. *Steady-state concentration during a 250-mg/m² IV infusion given over 24 h to adult cancer patients.

(Continued)
### TABLE AII–1 PHARMACOKINETIC DATA (CONTINUED)

| Paliperidone* |  
| --- | --- |
| 28 (oral ER)a,b,c |  
| 59 (51–67) (oral ER) | 74 |
| 3.70 ± 1.04d | 9.1d (oral ER) |
| ↓ LD | ↑ LDc |
| 25–49 days (IM PP)d | 13 days (IM PP) |

*Paliperidone, otherwise known as the 9-hydroxy active metabolite of risperidone, is marketed as an oral extended-release (ER) tablet (Invega) or in the form of its water-insoluble palmitate ester as a once-monthly long-acting IM injection (Invega Sustenna). Paliperidone is a racemate; its enantiomers have similar pharmacological profiles. The (±) -and (−)-enantiomers of paliperidone interconvert, reaching an AUC (±) to (−) ratio of ~ 1.6 at steady state. High-fat/high-caloric meal increased Cmax and AUC by 60% and 54%, respectively. No data on the absolute bioavailability of IM paliperidone palmitate (IM PP). The initiation regimen for Invega Sustenna (234 mg/156 mg in the deltoid muscle on day 1/day 8) produces paliperidone concentrations matching the range observed with 6- to 12-mg oral ER paliperidone. At steady-state during once-daily doses of 3 mg, assuming an average body weight of 73 kg, Vss is estimated from CL/F and t1/2. Patients with moderate hepatic impairment showed a modest increase in clearance and plasma free fraction with no significant change in unbound AUC. The apparent long terminal t1/2 of paliperidone following IM depot injection reflects the slow dissolution of paliperidone palmitate and release of active paliperidone.

| Pantoprazole* |  
| --- | --- |
| 77 (67–89) | 98 |
| 2.8 ± 0.9 | 0.17 ± 0.04 |
| ↓ LD | ↑ LD |
| 2.6 ± 0.9 | 2.5 ± 0.7 μg/mLc |

*Pantoprazole is available as a racemic mixture of (+) and (−) isomers. Pantoprazole is cleared primarily by CYP2C19 (polymorphic)-dependent metabolism. Poor metabolizers (PM) exhibit profound differences in CL (lower) and t1/2 (higher) compared to extensive metabolizers (EM). In CYP2C19 EM, no significant differences in the pharmacokinetics of (+) and (−) pantoprazole were observed, whereas in CYP2C19 PM, the CL of (−) pantoprazole was significantly greater than that of (+) pantoprazole. No unchanged drug recovered in urine. Following a single 40-mg oral dose.

| Paroxetine |  
| --- | --- |
| Dose dependent* | ≤ 2 |
| 95 | 8.6 ± 3.2b |
| ↓ LD, Aged | 17 ± 10c |
| EM: ~130 nM | 17 ± 3d |
| PM: ~220 nM | 5.2 ± 0.5c |

*Metabolized by CYP2D6 (polymorphic); undergoes time- and dose-dependent autoinhibition of metabolic CL in extensive metabolizers (EM). CL/F reported for multiple dosing in EM. Single-dose data are significantly higher. In CYP2D6 poor metabolizers (PM), CL/F = 5.0 ± 2.1 ml/min/kg for multiple dosing. Vss/F reported for multiple dose in EM. In PM, t1/2 = 41 ± 8 h. Estimated mean Cmax following a 30-mg oral dose given once daily for 14 days to adults phenotyped as CYP2D6 EM and PM. There is a significant disproportional accumulation of drug in blood when going from single to multiple dosing due to autoinactivation of CYP2D6.

| Phenobarbital |  
| --- | --- |
| 100 ± 11 | 24 ± 5a |
| 51 ± 3 | 0.062 ± 0.013 |
| ↓ Neo | ↑ Neo |
| 99 ± 18 | 2–4b |
| 13.1 ± 4.5 μg/mLb |

*Phenobarbital is a weak acid (pKa = 7.3); urinary excretion is increased at an alkaline pH; it also is reduced with decreased urine flow. Mean steady-state concentration following a 90-mg oral dose given daily for 12 weeks to patients with epilepsy. Levels of 10–25 μg/mL provide control of tonic-clonic seizures, and levels of at least 15 μg/mL provide control of febrile convulsions in children. Levels > 40 μg/mL can cause toxicity; 65–117 μg/mL produce stage III anesthesia—comatose but reflexes present; 100–134 μg/mL produce stage IV anesthesia—no deep tendon reflexes.

| Down arrow for ↓ RD       |                      |                     |                      |                  |                |              |                  |

*Bioavailability does not vary with dose up to 600 mg. T½ is delayed from 1 to 3 h and Cmax decreased by 25%–30% when pregabalin is given with food. No change in AUC or extent of absorption is noted. *Pregabalin undergoes minimal metabolism, an N-methylated metabolite has been identified in urine and accounts for 0.9% of oral dose. *Mean renal clearance in healthy young subjects ranges from 67 to 81 mL/min and assuming 70-kg body weight. Pregabalin pharmacokinetics is dose independent and predictable from single to multiple dosing. *Pregabalin clearance is proportional to CLcr hence, dosage can be adjusted in accordance to CLcr in renal dysfunction. Plasma pregabalin decreased by ~ 50% after 4 h of hemodialysis. *Steady-state concentration in healthy subjects receiving 200-mg pregabalin every 8 h.*

**Absorption**

- Data from patients undergoing elective surgery and healthy volunteers. Propofol is extensively metabolized by UGTs. For intravenous administration only. *Fraction bound in whole blood. Concentration dependent: 98.8% at 0.5 μg/mL and 98.3 at 32 μg/mL.*
- *CL and central volume decreased in children 1–3 years of age.*
- *CL and central volume decreased in elderly patients.*
- *A much longer terminal t<sub>1/2</sub> was reported following prolonged intravenous infusion.*
- *Concentration producing anesthesia after infusion to steady state (SS) and at emergence (E) from anesthesia.*

**Pseudoephedrine**

- Data from healthy adult male and female subjects.
- At a high urinary pH (>7.0), pseudoephedrine is extensively reabsorbed. t<sub>1/2</sub> increases, and CL decreases.

**Pyrazinamide**

- Pyrazinamide is hydrolyzed in the liver to an active metabolite, 2-pyrazinoic acid. Reported peak 2-pyrazinoic acid concentrations range from 0.1- to 1-fold that of the parent drug.
- *Absolute bioavailability is not known, but the drug is well absorbed based on recovery of parent drug and metabolites (70%).* Recovery of unchanged drug following an oral dose; the recovery of pyrazinamide is 37 ± 5%.

<sup>k</sup>The absolute oral bioavailability of raltegravir has not been determined. This minimum extent of oral absorption is based on recovery of radioactivity in urine following oral administration of <sup>14</sup>C-labeled raltegravir in healthy human subjects. <sup<k>Selephantegravir undergoes O-glucuronidation mediated largely by UGT1A1 and to a lesser extent by UGT1A3 and UGT1A9. Raltegravir AUC is only modestly elevated in individuals with <sup>14</sup>C-labeled raltegravir in healthy human subjects. <sup>k</sup>Selephantegravir undergoes O-glucuronidation mediated largely by UGT1A1 and to a lesser extent by UGT1A3 and UGT1A9. Raltegravir AUC is only modestly elevated in individuals with a 400-mg oral dose. Apparent oral clearance (CL/F) is listed. <sup>j</sup>Plasma concentration time course of raltegravir exhibits multiphasic washout kinetics. Initial (α) and terminal (β) t<sub>1/2</sub>s are reported because the early phase accounts for a large portion of the AUC from time 0 to ∞. Median for T<sub>max</sub> and geometric mean (95% confidence interval) for C<sub>max</sub> following a 400-mg twice-daily monotherapy regimen for 10 days in treatment-naïve patients with HIV-1 infection.

<sup>a</sup>Ramelteon undergoes primary oxidative metabolism followed by glucuronidation as secondary metabolism. CYP1A2 is the major enzyme involved in oxidative metabolism; CYP3A and CYP2C9 also are involved as minor enzymes. Remarkable elevation in C<sub>ss</sub> and AUC were observed with the concurrent administration of the strong CYP1A2 inhibitor iloprost. The M-II metabolite contributes to the hypnotic effects of ramelteon. M-II has 1/5th to 1/10th the affinity of ramelteon as an agonist for the melatonin receptors (MT-1 and MT-2); however, it circulates at 20- to 100-fold higher concentrations relative to ramelteon. Poor systemic availability of ramelteon is due to extensive first-pass metabolism. C<sub>ss</sub> and AUC are elevated by a high-fat meal; T<sub>1/2</sub> is slightly delayed. Calculated assuming 70-kg body weight. Although note shown, interindividual variability is notably large. Four- and 10-fold elevation in AUC in mild and moderate hepatic impairment. P = parent drug. M = M-II metabolite. C<sub>ss</sub> following a single 16-mg oral dose of ramelteon in young adult subjects. There is no measurable accumulation of parent drug or active metabolite because of their short elimination T<sub>1/2</sub>.

<sup>b</sup>Hydrolyzed to its active metabolite, ramiprilat (RT). Pharmacokinetic data for ramipril (R) and RT following oral and intravenous R administration are presented. Based on plasma AUC of R and RT after intravenous and oral R administration. Following an oral dose of R, CL/F of R calculated from reported AUC data. No data available; mean renal CL of RT is ~1.1 mL/min/kg. T<sub>1/2</sub> for the elimination phase reported. A longer terminal T<sub>1/2</sub> of ~120 h most likely corresponds to the release of drug from ACE; contributes to the duration of effect but does not contribute to systemic drug accumulation. Following a single 10-mg oral dose.

<sup>c</sup>Following a single 150-mg oral dose given to healthy adults. IC₅₀ for inhibition of gastric acid secretion is 100 ng/mL.

<sup>a</sup>Active desacetyl metabolite. <sup>b</sup>Absolute bioavailability is not unknown, although some studies indicate complete absorption. Such reports presumably refer to rifampin plus its desacetyl metabolite because considerable first-pass metabolism is expected: t<sub>1/2</sub> is shorter (1·7 ± 0·3) and CL/F is higher after repeated administration. Rifampin is a potent enzyme (CYP3A and others) inducer and appears to autoinduce its own metabolism. <sup>c</sup>Not observed with 300-mg doses, but pronounced differences with 900-mg doses: t<sub>1/2</sub> is longer with high single doses. Following a 600-mg dose given once daily for 15–18 days to patients with tuberculosis.

<sup>a</sup>The active metabolite, 9-hydroxyrisperidone, is the predominant circulating species in extensive metabolizers and is equipotent to parent drug. 9-Hydroxyrisperidone has a t<sub>1/2</sub> of 20 ± 3 h. In extensive metabolizers, 55 ± 7% of an intravenous dose is excreted as this metabolite; its elimination is primarily renal and therefore correlates with renal function. Formation of 9-hydroxyrisperidone is catalyzed by CYP2D6. <sup>b</sup>Parameters reported for extensive metabolizers. In poor metabolizers, F<sub>r</sub> is higher. <sup>c</sup>20% of an intravenous dose is excreted unchanged. 10% as the 9-hydroxy metabolite; CL is slightly < 1 mL/min/kg, and t<sub>1/2</sub> is similar to that of the active metabolite. <sup>d</sup>20 h. <sup>e</sup>For 9-hydroxyrisperidone. <sup>f</sup>Changes in elderly subjects due to decreased renal function affecting the elimination of the active metabolite. <sup>g</sup>Mean steady-state C<sub>min</sub> for risperidone (R) and total active (TA) drug, risperidone + 9-OH-risperidone, following a 3-mg oral dose given twice daily to patients with chronic schizophrenia. No difference in total active drug levels between CYP2D6 extensive and poor metabolizers.

</tbody>
</table>

**Sofosbuvir** is sequentially metabolized to a pharmacologically active nucleoside analogue triphosphate; the active metabolite is undetected in plasma. The first hydrolytic step appears to be rapid (much of it may occur during first pass), yielding the intermediate metabolite GS-566500, which can either be fully activated by kinase(s) to GS-461203 or inactivated by phosphatase activity to GS-331007. The absolute oral bioavailability of sofosbuvir in humans is not known. Administration with a high-fat meal increases systemic sofosbuvir exposure by 67%–91%, although this fraction is not thought to be clinically meaningful. **3.5% of the oral dose is recovered as unchanged sofosbuvir in urine; the true fraction excreted unchanged may be much higher, depending on the absolute bioavailability.** Also reported to be 62%–65% based on in vitro ultrafiltration experiments. **(Mean) 25th and 75th quartiles or CV%) reported following administration of 400 mg oral sofosbuvir, given once a day for 27 days. Systemic exposure (AUC) of sofosbuvir and GS-566500 increased 171% and 244%, respectively, in patients with severe renal impairment; smaller increases seen with less severe disease.**

**Sorafenib** is cleared by CYP3A- and UGT1A9-dependent metabolism. **<sup>c</sup>**Primarily bound to α1-acid glycoprotein. **<sup>d</sup>**Dose reduction is advised in patients with severe renal impairment (CL<sub>F</sub> < 30 mL/min), in whom a 2-fold reduction in clearance and prolongation in t<sub>1/2</sub> are expected. **<sup>e</sup>**At steady state following 21 days of dosing with 10 mg once daily.

**Sotalol** is available as a racemate. The enantiomers contribute equally to sotalol’s antiarrhythmic action; hence, pharmacokinetic parameters for total enantiomer mixture are reported herein. **<sup>c</sup>**Adrenergic receptor blockade resides solely with S(+)-isomer. **<sup>f</sup>**Following 80 mg, twice-a-day dosing to steady state.

**Spironolactone** is extensively metabolized; it has three known active metabolites: canrenone (C), 7α-thiomethylspironolactone (TS), and 6β-hydroxy-7α-thiomethylspironolactone (HTS). **<sup>c</sup>**Absolute bioavailability is not known; old values reported in the literature were based on nonspecific assays for C; likely to exhibit first-pass metabolism. **<sup>d</sup>**AUC of parent drug and metabolites increased when 5 taken with food. **<sup>f</sup>**Measured after an oral dose. **<sup>g</sup>**Binding of S and its active metabolites. **<sup>h</sup>**CL<sub>F</sub>/V<sub>0</sub>-<sub>1</sub> and t<sub>1/2</sub> calculated following a single 400-mg oral dose assuming 70-kg body weight.

</tr>
</tbody>
</table>

*Temsirolimus, a water-soluble ester analogue of sirolimus or rapamycin, is available for intravenous use. Following intravenous administration, temsirolimus is converted to sirolimus; blood AUC of sirolimus is 3-fold higher than that of temsirolimus at the recommended dose of 25 mg for the treatment of advanced renal cell carcinoma. Both temsirolimus and sirolimus inhibit mTOR kinase activity and undergo oxidative metabolism mediated by CYP3A. Recovery of radioactivity after a single intravenous dose of [14C]–temsirolimus. Both temsirolimus and sirolimus partition extensively into blood cells; a major fraction of temsirolimus and sirolimus in plasma is bound to plasma proteins. Based on Cl.f of 16.1 ± 2.5 L/h and Vss of 232 ± 36 L at a dose of 25 mg, assuming an average body weight of 70 kg. All pharmacokinetic assessments are based on whole-blood concentrations. Following the first dose of a 25-mg/week regimen.

### Tenovir

| 25mg      | 82 ± 13 | <1   | 2.6 ± 0.9b  | 0.6 ± 0.1c  | 8.1 ± 1.8de  | 2.3e  | 326 ng/mLf             |
| Food      | ↓ RD    | ↑ RD  |            |            |               |       |                  |

Tenovir is formulated as an ester prodrug, VIREAD (tenofovir disoproxil fumarate), for oral administration. Bioavailability under fasted state reported; increased to 39% with high-fat meal. Data reported for steady-state 3-mg/kg IV dose given once a day for 2 weeks to HIV-1–infected male and female adults. Slightly higher Cl.f with single intravenous dose. Longer apparent plasma t1/2 (17 h) reported for steady-state oral dosing; this may reflect a longer duration of blood sampling; also, phosphorylated “active” metabolite exhibits a longer intracellular t1/2 (60 h). Following a 300-mg oral-dose given once a day with a meal to steady state.

### Terazosin

| 82         | 11–14   | 90–94 | 1.1–1.2     | 1.1         | 9–12         | 1.7m     | 16 ng/mL3            |
| Oral: 4    | IV: 16.4 ± 1.2 μg/mL3 | Oral: 2.3 ± 0.2 μg/ mL3 |

Plasma Cl.f reportedly reduced in patients with hypertension. Following a 1-mg oral dose (tablet) given to healthy volunteers.

### Tetracycline

| 77         | 58 ± 8  | 65 ± 3 | 1.67 ± 0.24 | 1.5 ± 0.1c  | 10.6 ± 1.5  | 1.7          | 16 ng/mL3            |
|            | 1.0     |       |            |            |             |               |                  |

Vss reported. Following a single 10-mg/kg IV dose or a single 250-mg oral dose (taken after a fast and with water).

### Thalidomide

| —         | <1      | —     | 2.2 ± 0.4e  | 1.1 ± 0.3c  | 6.2 ± 2.6c  | 2.0 ± 1.4d   | 2.0 ± 0.6 μg/mLf    |
| Food      | ↑ HD,   | ↑ HD  |            |            |             |               |                  |

Data from healthy male subjects. Similar data reported for asymptomatic patients with HIV. No age or gender differences. Thalidomide undergoes spontaneous hydrolysis in blood to multiple metabolites. Absolute bioavailability is not known. Altered absorption rate and extent, Hansen disease (HD). Cl.f, Vss, f, and t1/2 reported for oral dose. Following a single 200-mg oral dose.

### Tolerodine

| EM: 26 ± 18 | EM: Negligible | T: 96.3 | EM: 9.6 ± 2.8 | EM: 1.7 ± 0.4 | EM: 2.3 ± 0.3 | EM: 1.2 ± 0.5c | EM: 5.2 ± 5.7 ng/mLf |

Data from healthy adult male subjects. No significant gender differences. Tolerodine (T) is metabolized primarily by CYP2D6 to an active (100% potency) metabolite, 5-hydroxymethyl tolerodine (5-HM), in extensive metabolizers (EM); t1/2 5-HM = 2.9 ± 0.4 h. Also metabolized by CYP3A to an N-desalkyl product, particularly in poor metabolizers (PM). CL.f reduced and AUC 5-HM unaltered, increased hepatic cirrhosis. Following a 4-mg oral dose given twice daily for 8 days, Cl.f of 5-HM was 5 ± 3 ng/mL for EM.

<sup>a</sup>Tramadol (T) is available as a racemic mixture. At steady state, the plasma concentration of (+) (1R,2R)-tramadol is ~30% higher than that of (-) (1S,2S)-tramadol. Both isomers contribute to analgesia. Data reported are for total (+ and –) T. T is metabolized by CYP2D6 to an active O-desmethyl metabolite (M1); there are other CYP-catalyzed metabolites.

<sup>b</sup>Recovery following an oral dose was reported. Following a 100-mg immediate-release tablet given every 6 h for 7 days.

<sup>a</sup>Studies included concurrent administration of sulfamethoxazole and variation in urinary pH; these factors had no marked effect on the CL, V<sub>ur</sub>, and t<sub>1/2</sub> of trimethoprim.

**Valacyclovir**

<sup>a</sup>Data from healthy male and female adults. Valacyclovir is an L-valine prodrug of acyclovir. Extensive first-pass conversion by intestinal (gut wall and luminal) and hepatic enzymes. Parameters refer to acyclovir (A) and valacyclovir (V) following V administration. See Acyclovir for its systemic disposition parameters. <sup>b</sup>Bioavailability of A based on AUC of A following intravenous A and a 1-g oral dose of V. Urinary recovery of A is dose dependent (78% and 44% following 100-mg and 1000-mg oral doses of V and 87% following intravenous A). <sup>c</sup>CL/F reduced, moderate-to-severe renal impairment (drug cleared by hemodialysis). Following a single 1-g oral dose of V.

Valganciclovir (V) is an ester prodrug for ganciclovir (G). It is rapidly hydrolyzed with a plasma t₁/₂ = 0.5 h. G and V data following oral V dosing for male and female patients with viral infections are reported. See Ganciclovir for its systemic disposition parameters. \*Increased and more predictable bioavailability of G when V is taken with a high-fat meal. \*The apparent t₁/₂ of G is increased in patients with renal impairment. \*Following a single 360 mg oral dose of V taken without food. \*Following a 900 mg oral dose of V taken once daily with food to steady state.

**Valproic Acid**\*

| 100 ± 10⁴ | 1.8 ± 2.4 | 93 ± 1² | 0.11 ± 0.02⁴ | 0.22 ± 0.07 | 14 ± 3⁴ | 1–4⁴ | 34 ± 8 μg/mL⁴ |
|↓ RD, LD, Preg, Aged, Neo | ↑ Child | ↑ LD, Neo | ↑ LD, Neo | ↓ Child | | |

\*Valproic acid is available either as the free acid or stable coordination compound comprised of sodium valproate and valproic acid (divalproex sodium). \*Systemic availability of valproic acid is the same after molar equivalent oral doses of free acid and divalproex sodium. \*Dose-dependent; value shown for daily doses of 250 and 500 mg. At 1 g daily, percentage bound = 90% ± 2%. \*Data for multiple dosing (500 mg daily) reported. Single-dose value: 0.14 ± 0.04 mL/min/kg, t₁/₂ = 9.8 ± 2.6 h. Total CL is the same at 100 mg daily, although CL of free drug increases with multiple dosing. Valproate is eliminated mainly by glucuronidation. \*Increased CL and decreased t₁/₂ from enzyme induction following concomitant administration of other antiepileptic drugs. \*Average concentration following a 250 mg oral dose (capsule, Depakene) given twice daily for 15 days in healthy male adults. A therapeutic range of 50–150 μg/mL is reported.

Valproic Acid is available either as the free acid or stable coordination compound comprised of sodium valproate and valproic acid (divalproex sodium).

**Valsartan**\*

| 23 ± 7 | 29.0 ± 5.8 | 95 | 0.49 ± 0.09⁴ | 0.23 ± 0.09 | 9.4 ± 3.8 | 2 (1.5–3)⁴ | 1.6 ± 0.6 μg/mL⁴ |
|↓ Food | | | | | | | |

\*Data from healthy adult male subjects. No significant gender differences. \*Valsartan is cleared primarily by biliary excretion. \*CL/F reduced, mild-to-moderate hepatic impairment and biliary obstruction. \*Following a single 80-mg oral dose (capsule).

**Vancomycin**

| —² | 79 ± 11 | 30 ± 11 | CL = 0.79CL₉ + 0.22 | 0.39 ± 0.06 | 5.6 ± 1.8 | — | 18.5 (15–25) μg/mL² |
|↓ RD, Aged, Neo | ↓ Obes | ↑ RD, Aged | ↓ Obes | |

\*Very poorly absorbed after oral administration, but used by this route to treat *Clostridium difficile* and staphylococcal enterocolitis. \*Following a dose of 1000 mg IV (1-h infusion) given twice daily or a 7.5 mg/kg IV (1-h infusion) given four times daily to adult patients with staphylococcal or streptococcal infections. Levels of 37–152 μg/mL have been associated with ototoxicity.

**Vardenafil**\*

| 15 (8–25) | 2–6 | 93–95 (parent and M1) | 56 | 3.0⁴ | 4–5 (parent and M1) | 0.7 (0.25–3)⁴ | 19.3 ± 1.7 ng/mL⁴ |
| Vardenafil is primarily metabolized by CYP3A with minor involvement of CYP2C9. The major oxidative metabolite (M1), a product of N-demethylation at the piperazine ring, is a less potent phosphodiesterase (PDE) 5 inhibitor and circulates at a level 28% that of the parent drug. It contributes only 7% of the in vivo activity of vardenafil. \*V₉ of 208 L, assuming 70-kg body weight. \*Following a single 20-mg dose. There is no change in pharmacokinetics between single and multiple dosing.

| *87.1 ± 5.5% of radioactivity is excreted in urine after an oral dose of [14C] varenclline. Minimal first-pass metabolism is expected. Varenclline is cleared mostly by renal excretion with minimal metabolism. Organic cation transporter 2 (OCT2) is involved in renal tubular secretion, as evidenced by inhibition of varenclline renal clearance by cimetidine, a known OCT2 inhibitor. CL/F and V/F estimated from steady-state AUC and t1/2 during 1 mg twice-daily dosing of varenclline in healthy adult smokers and assuming an average body weight of 70 kg. After the first dose of a multiple-dosing regimen. An accumulation factor of 2.8 ± 0.73 was reported.

| **Venlafaxine, Desvenlafaxine** |                       |                     |                      |                 |                  |              |                  |
| 10–45                       | V: 4.6 ± 3.0           | V: 27 ± 2           | 22 ± 10f             | 7.5 ± 3.7e      | 4.9 ± 2.4e       | 10.3 ± 4.3f  | ODV: 2.8 ± 0.8c  |
| ODV: 29 ± 7e                | ODV: 30 ± 12e          |                     |                      |                 |                  |              | ODV: 397 ± 81 ng/mLc |

- Venlafaxine (V) is available as a racemic mixture; antidepressant activity resides with the (–)-enantiomer and its equipotent O-desmethyl metabolite (formation catalyzed by CYP2D6–polymorphic). Parameters for the derived O-desmethylvenlafaxine (ODV) are included. O-Desmethyl metabolite is marketed as desvenlafaxine in an extended-release formulation as a successor to V. It has a higher oral bioavailability (80%), with a t1/2 of 7.5 h. Desvenlafaxine has a much lower CL (3.5 mL/min/kg) and a smaller Vz (3.4 L/kg).
- Its reported t1/2 matches that observed for metabolite derived from V. Values for ODV after V dosing. CL/F and V/F reported. Mean data for V and ODV following a 75-mg oral dose (immediate-release tablet) given three times daily for 3 days to healthy adults. T1/2 for an extended-release formulation is 5.5 (V) and 9 (ODV) h.

| **Verapamil** |                       |                     |                      |                 |                  |              |                  |
| Oral: 22 ± 8 | <3                     | 90 ± 2              | 15 ± 6d             | 5.0 ± 2.1       | 4.0 ± 1.5e       | IR: 1.1d     | IR: 272 ng/mLe   |
| SL: 35 ± 13 |                       |                     |                      |                 |                  |              |                  |

- Racemic mixture; (–)-enantiomer is more active. Bioavailability of (+)-verapamil is 2.5-fold greater than that for (–)-verapamil because of a lower CL (10 ± 2 vs. 18 ± 3 mL/min/kg). Relative concentration of the enantiomers changes as a function of route of administration. (–) Active metabolite, norverapamil, is a vasodilator but has no direct effect on heart rate or P-R interval. At steady state (oral dosing), AUC is equivalent to that of parent drug (t1/2 = 9 ± 3 h). Multiple dosing causes a greater than 2-fold decrease in CL/F and prolongation of t1/2 in others. Verapamil is a substrate for CYP3A4, CYP2C9, and other CYPs and for the efflux transporter P-glycoprotein. Mean data following a 120-mg oral conventional tablet (IR) given twice daily or range of data following a 240-mg oral extended-release (XR) dose given once daily; both for 7–10 days to healthy adults. The dose of 240 mg contains 200 mg verapamil base, 40 mg of desethyl-verapamil, and 3 mg of 14α-hydroxy verapamil. A dose of 480 mg contains 280 mg verapamil base, 56 mg of desethyl-verapamil, and 7 mg of 14α-hydroxy verapamil.

| **Vincristine** |                       |                     |                      |                 |                  |              |                  |
| —             | 10–20                  | Low                 | 4.92 ± 3.01 L/h/m²   | 96.9 ± 55.7 L/m²d | 22.6 ± 16.7d     | —            | ~250–425 nM      |

- Data from adult male and female cancer patients. *Metabolized by CYP1A2 and excreted unchanged into bile (substrate for P-glycoprotein). CL reduced, cholestatic liver disease. t1/2, and Vz for terminal phase. Longer t1/2 (~95 ± 69 h) also reported. Following a 2-mg IV bolus dose.

| **Vinorelbine** |                       |                     |                      |                 |                  |              |                  |
| 27 ± 12d        | 11                     | 87 (80–91)          | 21 ± 7              | 76 ± 41d        | 42 ± 21d        | 1.5 ± 1.0     | 114 ± 43 ng/mLd  |

- For liquid-filled gelatin capsules. Elimination kinetics of vinorelbine follow a three-compartment model with extensive tissue distribution. Values for the terminal elimination phase are reported. Following a single 100-mg/m² oral dose (gel capsule). Following a single 300-mg/g IV infusion over 15 min.

*Metabolized mainly to an inactive N-oxide by CYP2C19 (major), CYP3A4, and CYP2C9. 1Elimination is dose and time dependent. Pharmacokinetic parameters determined at steady state are reported. Mean CL was reduced (64%), V<sub>ss</sub> reduced (32%), and t<sub>1/2</sub> increased (16%) with 12 days of twice-daily 3-mg/kg IV administration. Also, CL decreased 41% when dose was increased from 200 to 300 mg twice daily. 2CL reduced in patients with mild-to-moderate hepatic insufficiency. 3Following a 3-mg/kg oral dose given twice daily for 12 days. Following a 3-mg/kg IV infusion over 1 h given twice daily for 12 days.

*Recovery following oral administration. 1Approximately one-third of the dose is oxidized by CYP3A4, and the remainder undergoes reduction. 2A longer t<sub>1/2</sub> after oral dosing is rate limited by absorption; food decreases apparent t<sub>1/2</sub>. In the elderly, the t<sub>1/2</sub> is slightly longer. 3Following a 20-mg oral dose given twice daily for 8 days. 4Following a single 10-mg IM dose.

110t, 1073, 1073f
Na+ channel(s)
antiseizure drug modulation of, 303, 306,
307f, 323f
in cardiac cell at rest, 547–548, 548f, 549f
genes encoding, 308
in kidney, 458, 458f
ligand-gated, 44, 44f
local anesthetics and, 406–408, 408f
in neurotransmission, 123, 124, 125
structure and function of, 407f
voltage-gated, 240f
Na+ channel blockers, 450f, 570–571f
adverse effects of, 556, 558
antiarrhythmic effects of, 556, 557f,
570–571f
contraindications to, 560f
mechanisms of action of, 450f, 555, 557f
Na+–Cl− syptom inhibitors. See Thiazide
diuretics
NADH, 422, 427
NADH methemoglobin reductase deficiency,
980, 1079
Nadolol, 212t, 216, 221f, 503t
NAPD/NAPDH, 88, 88f, 422, 476, 803
Nafarelin, 780f, 781, 785t, 827, 829f, 1240f,
1245f
Nafillin, 1029, 1036f
Nafinone, 1100, 1282f
Na+-glucose transporter 2 (SGLT2) inhibitors,
879–880, 882f, 883f, 884f
Na+ intake, blood pressure and, 479, 479f
Na+ (K+)-symport inhibitors. See High-
cellulat diuretics; Loop diuretics
Na+/K+ ATPase (sodium pump), 446–448,
448f
inhibitors, 537, 539f
Nalbuphine, 369f, 370f, 375, 384f
Naldemedine, 930, 941f
Nalidixic acid, 1017
Nalmefene, 370f, 377, 384t, 430, 430t
Nalorphine, 370f
Naloxegol, 930, 941f
Naloxone, 315, 359f, 370f, 376–377, 383, 384f
Naltrexone, 359, 370f, 376–377, 384t, 1360f
adverse effects of, 429–430
for alcohol use disorder, 429, 429f, 430t, 436
for opioid dependency, 377, 439
Naltirindole, 359f
NAMs (negative allosteric modulators), 150
Naphazoline, 1260, 1263
Naproxen, 698, 699f, 700, 707t, 1360t
Naratriptan, 233, 240f
Narcolepsy, 207
Narcotic, 356
Naronapride, 925
Nasal congestion, 206–207
Natalizumab, 629, 650, 650f, 652t, 661t
Natamycin, 1258, 1259f
Nateglinide, 77, 874, 875, 883f, 884t
Natriuretic peptides and receptors, 46, 458–
459, 496f. See also specific peptides
NATs. See N-acetyltransferases (NATs)
Natural killer (NK) cells, 621, 625
Nausea and vomiting. See also Antiemetic
agents
after general anesthesia, 387–388
with alkylating agents, 1172
with cisplatin, 1176
with GLP-1 inhibitors, 878
with opioids, 367
pathophysiology of, 934–935, 935f
NCC, 309
NE. See Norepinephrine (NE)
Nebivolol, 212t, 213t, 218f
for heart failure, 534, 534t, 543t

Sofosbuvir/daclatasvir, 1130–1131, 1134f
Sofosbuvir/ledipasvir, 1130, 1134f
Sofosbuvir/simeprevir, 1131, 1134f
Sofosbuvir/velpatasvir, 1131–1132, 1134f
Soft tissue infections. See Skin and soft tissue infections
Soft-tissue sarcoma, 1210, 1220
Solifenacin, 102, 102f
Solute carrier (SLC) superfamily. See SLC transporter superfamily
Soman, 167t, 168, 174r
Somatic motor nerves, 115, 119–120, 119f
Somatostatin (SST), 260t, 772t, 774, 774f, 864, 883, 909
 analogous, 777–777, 883, 885t, 932–933, 941f
Somatotropic family of hormones, 772, 773r. See also specific hormones
Somatomedin, 777–778, 784t
Sonidegib, 1210, 1288
Sorafenib, 799, 800t, 1233t, 1372t
Sorbitol, 928, 940t
Sotalol, 31, 552r, 558r, 559, 560t, 563t, 570, 571t, 1372f
Sp1, 809
Spacer chambers, 730
Sparfloxacin, 1015
Spasticity, 336
Specificity, of drug, 31–33
Spinal and bulbar muscular atrophy (Kennedy disease), 835
Spinal anesthesia, 415–416, 418f
Spinal cord
injury, 858
opiate action in, 365
Spinomas, 1283, 1292t
Spiramycin, 988, 996t
Spironolactone, 456–458, 456t, 469t, 1372t
adverse effects of, 458, 512, 839
as androgen receptor inhibitor, 839
for dermatologic disorders, 827, 1290, 1294f
for heart failure, 535, 537t, 543f
for hypertension, 512
Spleen, 622
Sporotrichosis, 1089t, 1090, 1093
Veno-occlusive disease (VOD), of liver, 1172, 1172f, 1174
Ventilation-perfusion mismatch, with β₁
agonists, 732, 732f
Ventilatory stimulants, 744
Ventricular fission, 552f, 553, 554f, 556f
Ventricular tachycardia, 552f, 553, 554f, 556f
Verapamil, 503f, 554, 558f, 559, 563f, 571f, 1377f
adverse effects of, 498, 552f, 559
contraindications to, 560f
drug-drug interactions of, 498, 611
history of, 495b
for hypertension, 516, 524f
for ischemic heart disease, 495–498, 495f, 497f
for pulmonary arterial hypertension, 582
Vernakalant, 570
Verruca vulgaris, 1115
Verteporfin, 1266, 1266f
Vertigo, 718
Very low-density lipoproteins (VLDLs), 606, 607f
Vesamicol, 127f, 128, 141
Vesicular ACh transporter (VACHT), 127f, 128
Vesicular monoamine transporter (VMAT2) amphetamine and, 204
bupropion and, 271
in catecholamine synthesis, 132–133, 134f, 137
in dopamine synthesis, 236f, 329f
in 5HT synthesis, 225
inhibitors, 65, 183, 235, 290, 291, 335, 515
Vesiculin, 128
Vesnarinone, 542f
Vestibular toxicity, 1044
VHL (von Hippel-Landau) protein, 752
Vigabatrin, 310f, 320, 322, 324f
Vilanterol, 201, 731
Vilanterol/fluticasone furoate, 746f
Vilanterol/umeclidinium, 736, 745f
Vilazodone, 234, 241f, 275f
Vildagliptin, 874f, 879, 883f, 884f
Viloxazine, 271f
Vinblastine, 1186–1187, 1199f
for dermatologic disorders, 1284, 1284f, 1292f
Vinca alkaloids, 1186–1187, 1186f, 1188f, 1199f
Vincristine, 1074f, 1186–1187, 1199f, 1377f
Vinorelbine, 1186–1187, 1199f, 1377f
VIP (vasoactive intestinal peptide), 144–145, 574, 575f, 737
Viral hepatitis. See Hepatitis A virus (HAV); Hepatitis B virus (HBV); Hepatitis C virus (HCV)
Viral keratitis, 1257
Viral retinitis, 1257
Viridans streptococci, 1027
Virus(es). See also specific viruses
antimicrobial susceptibility tests in, 961 quasi-species, 966
replication of and drug targets in, 1105, 1106f
Visceral afferent fibers, 115
Viscoelastic substances, 1264
Vismodegib, 1210, 1288
Vitamin A, 1267f, 1268–1269
Vitamin B, (thiamine) deficiency, 425, 1267f
Vitamin B₁, (pyridoxine), 761, 938, 942f, 1077
deficiency of, 1267f
Vitamin B₂
deficiency of, 763, 1267f
discovery of, 761b
dolic acid and, 761f–762f, 761f
in human health, 762–763, 763f
structure of, 762f
therapy with, 763–764
Vitamin C (ascorbic acid)
deficiency of, 1267f
iron uptake and, 759
Vitamin D, 892–893, 892b, 892f, 896–897, 902
adverse effects of, 897
analogues of, 897, 903f
chemistry and occurrence of, 892
deficiency of, 895
disorders of, 895–896. See also specific
diseases of, 894, 895
human requirements for, 888f, 892
mechanisms of action of, 893
receptor (VDR), 98f
Vitamin D-binding protein, 892
Vitamin E (tocopherol), 1301, 1301f
deficiency of, 1267f
Vitamin K, 599–600, 599f, 602f
antagonist. See Warfarin
cycle, 592f
deficiency of, 1267f
Vitreous, 1255
Vitreous substitutes, 1264, 1265f
VKORC1, warfarin metabolism and, 108, 108f, 592, 592f, 593, 593f
VLDLs (very low-density lipoproteins), 606, 607f
VMA (vanillyl mandelic acid), 136f, 137
VMAT2. See Vesicular monoamine transporter (VMAT2)
VNUT, 133
Voglibose, 879, 884f
Voltage-gated channels, 40t, 43, 44f. See also specific channels
Volume of distribution (V), 23, 23b, 24f, 1327, 1329
Vomiting. See Nausea and vomiting
Von Hippiel-Landau (VHL) protein, 752
Von Willebrand factor, 463
Vorapaxar, 598, 602f
Voriconazole, 1092f, 1095–1096, 1102f, 1378f
drug-drug interactions of, 1093f, 1094f,
disorders of, 1095–1096
for ophthalmic use, 1259f
Vorinostat, 1230, 1288
Vorozole, 813, 829f
Vortioxetine, 269, 271, 276f
VX, 167f, 168, 174f
W
Warfarin, 592–593, 592f, 601f, 1378f
adverse effects of, 594
drug-drug interactions of, 38, 593–594, 612, 691, 704f, 1206, 1207
hypersensitivity to, 594
pharmacogenetics of, 58, 108, 108f, 110, 593f
poisoning/overdose, 57f
in pregnancy, 594
Water intoxication, 468
Water pollution, 1302
Weed. See Marijuana
Weight gain
with antipsychotics, 292, 297
with metformin, 875
with thiazolidinediones, 876
Weight reduction, 207
Wernicke-Korsakoff syndrome, 425
West African trypanosomiasis (T. brucei gambiense), 988–989, 990, 991, 994, 997f
Whole-bowel irrigation, 62
Wilms tumor, 1190
Withdrawal syndromes, 435–436. See also specific drugs
Within-patient variability, 599
Wolf-Chaikoff effect, 798
Wolf-Parkinson-White (WPW) syndrome, 552–553, 553f, 554f, 560f
World Health Organization (WHO), analgesic ladder, 379f
Wucheria bancrofti, 1003
X
Xanthine, 703f
Xanthine oxidase inhibitors, 703–705, 707f
 Xenobiotics, 85–87, 87f
Xenon, 389, 393f, 396, 402f
Xerophthalmia, 1269
Xerostomia, 152
X-linked hypophosphatemia (XLH), 895
Y
Yellow fever virus vaccine, 668
Yersinia pestis. See Plague
Yohimbine, 208, 210
Z
Zafirlukast, 675, 740–741, 741f, 746f
Zalcitabine, 1140, 1141f
Zaleplon, 341, 345, 352f
Zanamivir, 108f, 1113f, 1114, 1116f
Z compounds (benzodiazepine receptor agonists), 345, 352f
Zero-order kinetics, 20, 26f, 959
Ziconotide, 383
Zidovudine, 754, 1139–1140, 1140f, 1141f,
1142f, 1154f, 1378f
Zileuton, 675, 740–741, 741f, 746f
Zimeldine, 271f
Zinc deficiency, 1267f
Ziprasidone, 282, 283
Zolpidem, 341, 345, 352f, 1378f
Zonisamide, 310f, 320, 323f, 1378f
Zopiclone, 345, 1345f
Zoster. See Herpes zoster virus (HZV)
Zotepine, 284f
Zuclopenthixol, 284f
